Projective identification describes the unconscious processes of projection of unresolved parental conflicts onto a child, who assumes an identity based on a historically assigned role. Assumption of this role interferes with the child's appropriate identity formation. Traumatic events such as child neglect and physical or sexual abuse in the early history of the family can result in the repetition of such traumatic situations in subsequent generations. "Parentification," another impediment to the child's development, assigns a parental role to a child and deprives him or her of age-appropriate experiences.

Although many schools of family therapy recognize the significance of the separation–individuation process for adolescent family members, few of them describe the intricate network of developmental failures within the family and the adolescent that undermine the separation–individuation process. Stierlin (28) proposed that binding, delegating, and expulsion are three ways that families negotiate a pathologic separation to overcome the fear of prolonged fusion. In the binding mode, the excessive binding of the family to the adolescent can force the growing adolescent into psychotic or suicidal behavior to free himself or herself from the family unit. In the intricate delegating mode, the family allows the adolescent to depart from the family unit "on a long leash" to return periodically to share the tales of his or her exploits in order to compensate for the restricted life of the parents. In the expulsion mode, the adolescent is rejected by and extruded from the family to free him or her from the family unit.

TECHNIQUES

The literature on family therapy with children describes the clinical process and office arrangements that are most welcoming toward the children. The office should be equipped with toys that are conductive to imaginative play; paper and crayons provide unlimited possibilities for drawing and expression of fantasies. A special attempt should be made to include the children in the treatment process by using age-appropriate methods of communication for the child. Long and complex discussions discourage children from participating and should be avoided. The observational data on families with young children are especially significant. Techniques for family therapy with children have been described by Zilbach (29) and Chasin and White (30). Sholevar has described in detail the process of initial and diagnostic family interview (31).

Often, family therapy with children can disclose physical or emotional child neglect. When family support is potentially available, family intervention can mobilize and rehabilitate family resources to provide the necessary nurturance to

resume the child's developmental progress. When such resources are not present, enabling the family to search for an alternative living situation with the help of social agencies may be necessary (31,32).

FAMILY INTERVENTION WITH ATTENTION-DEFICIT HYPERACTIVITY DISORDER

Family interventions have been employed to reduce the core symptoms of attention-deficit hyperactivity disorder (ADHD). The reduction in negative interaction between the parents and children has been enhanced when parent therapy and family interventions were provided as a primary or adjunctive treatment (33–35). Parent training allows the parents to enhance the capacity of the ADHD child to focus, remain on task, solve problems, act prosocially with peers, and reduce impulsivity and aggression through cognitive processing. These are effective tools to strengthen the positive parent–child bonds and the ADHD child's fragile self-esteem by reducing negative and counterproductive parental behavior and enhancing skillful and goal-directed intervention by parents in potentially conflictual situations.

Multimodal Treatment Study of Children with ADHD is a comprehensive psychosocial treatment package of 30 parent training sessions, school visits, and teacher training with or without medication (33,36). The combined treatment exhibited the best results in control of ADHD core symptoms.

FAMILY THERAPY AND CONDUCT DISORDERS

Paterson et al. (37) described "coercive family processes" by which the parents, who generally lack management skills, initiate overly punitive and aggressive actions toward their children but withdraw in the face of strong opposition by the children. The coercive processes result in a high level of aggressive and uncontrollable behavior in the children. Subsequent research by Patterson et al. (37) focused on the relationship between aggressive behavior in children and depression in parents, particularly single mothers.

Other researchers also have studied the families of children with conduct disorders. Alexander, Barton, and Parsons (38–40) examined the function of aggressive behavior in the family and attempted to change the family's interactions from defensive to supportive interactions through functional in order to undermine conduct problems.

Functional family therapy (FFT), PMT, and multisystemic therapy (MST) have produced very encouraging therapeutic results with conduct disorders.

Parent Management Training

Forehand and Kotchick (41) and Patterson et al. in 1982 have produced extensive and empirically based interventions in PMT. Their approach has been applied in multiple settings by independent teams of investigators and has proved beneficial in altering oppositional/defiant behavior and conduct disorders, and enhancing prosocial behavior in children at home and in school. The preventive effect on younger siblings of children with conduct disorders also has been noted (37,41). PMT addresses the deficient parental management skills that are intimately correlated with antisocial behavior and arrested socialization in children. It teaches the parents to interact proactively and more productively with their children by reinforcing prosocial behavior rather than inadvertently rewarding deviant behavior (42–44).

The basic principles of PMT are accurate labeling of the child's behavior, emphasis on prosocial behavior, de-emphasis of disruptive behavior, administration of tangible reinforcers, use of nonviolent methods of "punishment" and anticipation/resolution of problems. The keystone targeted behavior of the child is noncompliance.

The interventions are based on positive reinforcement of prosocial behavior, use of time out, guidelines for attending/ignoring, shaping the desirable behavior (successive approximation of terminal behaviors), and enhancement of problem-solving, negotiations, and compromise formations. Coercive family processes (37) are identified and resolved through effective reinforcement.

Extensive research by numerous independent investigators in different settings has demonstrated the effectiveness of PMT over the control groups by generalization of therapeutic results in different settings, short-term and long-term beneficial outcomes. There has been a lowering of parental (maternal) depression and subsequent referral of younger siblings for antisocial behavior. The treatment has been less effective with "insular mothers" who are socially isolated, depressed, and have economic problems (45). A range of behavioral and cognitive interventions, enlargement of the social network, and medication in the case of parental depression can all help to enhance maternal functioning.

In response to the large number of delinquent children placed out of home, PMT has been applied to children in foster care. Oregon Treatment Foster Care (OTFC) is a family- and home-based treatment model that teaches effective parenting practices through close monitoring and limiting contact with deviant peer groups (46,47). This intervention has produced a reduction in rearrests, detention center placement, runaway behavior and improved relationships with biologic families in comparison to adolescents placed in conventional foster care.

FUNCTIONAL FAMILY THERAPY

FFT developed by Alexander et al. (38,40) attempts to alter defensive family

interactions to supportive ones in families of delinquent children through an integration of behavioral, structural/strategic techniques.

MULTISYSTEMIC THERAPY: MOVING BEYOND FAMILY THERAPY

In the past two decades, there have been many attempts to broaden the scope of family interventions to include multiple other systems. The MST of Henggeler et al. (48,49) is the most widely recognized and empirically validated intervention system of its kind. The target of the family-based intervention has been chronic, violent, or substance-abusing juvenile offenders at high risk for out-of-home placement. The intervention is based on the premise that the individual with CD is nested within a complex network of interconnected systems that encompass individual, familial, and extra-familial (peer, school, neighborhood) factors. The goal of MST is to empower parents with the skills and resources needed to raise their teenage children and to empower the youth to cope with family, peer, school, and neighborhood problems. The therapeutic approach provides support and skill building in the family and the youth to achieve this goal. It emphasizes building youth and family strength (protective factors) on an individualized and comprehensive basis to attenuate risk factors. The home-based model enhances service access and family retention in treatment. It has been applied with male and female African American and white adolescents between the ages of 12 and 17 years. The therapists have a low caseload and strong system of supervision supplemented by consultation to allow intensive intervention. The approximate length of the treatment is 4 months.

MST has produced strong evidence for program effectiveness in multiple controlled and randomized clinical trials with violent and chronic juvenile offenders.

They have demonstrated the following findings:

- Reduction in long-term rate of criminal offences
- Reduced rates of out-of-home placement
- Reduced rates of drug use and drug-related offenses
- Improvement in family functioning
- Decrease of other mental health problems
- A lower level of rearrest, reincarceration, and reduction in the days of out-of-home placement

MST as an alternative to psychiatric hospitalization at the time of crisis has produced an 85% reduction in days of hospitalization.

FAMILY INTERVENTION AND DEPRESSION

Depressed patients tend to be aversive to others and also feel victimized by them.

They frequently engage in escalating negative exchanges. Depressed patients and their family members tend to verbalize negative, subjective feelings more frequently than nondepressed couples, whose communications are more task oriented (50–54). The marriages of depressed women (or men) are characterized by friction, poor communication, a lack of affection, withdrawal, and a tendency for the nondepressed spouse to view his or her spouse as accusatory (50,52).

Children of depressed parents are at risk for many diagnosable psychological problems, a rate as high as 40% to 50% (52). The risk to children is increased if (1) the depressed person's spouse becomes depressed or is unavailable to the child, (2) there are marital problems or divorce (52), and (3) there is no supportive relationship with another adult.

Family-based interventions with depressed patients are based on an integration of family systems theory psychoeducational model, psychodynamic theory and attachment theory within a developmental model (53). The role of nondepressed parent in enhancing the coping capacity of the family is crucial (53).

Brent et al. (55) have reported that CBT is more effective than structural family therapy with depressed adolescents at the end of treatment but equally effective in 2-year follow-up. When methodologic issues are put aside, structural family therapy as practiced by the group may not have addressed crucial family issues for depressed adolescents such as poor attachment and low affective involvement between the parents and children. Beardslee and Schwoeri's (18) comprehensive preventive model to reduce the likelihood of transmission of depression from the parents to the children remains dominant in the field.

ANXIETY DISORDERS

A number of family variables have been implicated in anxiety disorders. They include overprotective and overly controlling parenting styles, parents modeling or reinforcing anxious and avoidant behaviors, and parental perception of excessive threats (56). CBT and behavioral family therapy have been compared in treatment of childhood anxiety disorders (57). The family therapy component included communication and problem-solving techniques and anxiety management methods for parents. The combination of CBT and BFT was significantly more effective than CBT alone, particularly with younger children and girls. In addition to a reduction in anxiety, there was an improvement in general functioning and enhancement in parental competence.

FAMILY THERAPY AND "PSYCHOSOMATIC" DISORDERS

Minuchin et al. (11) described several common characteristics among families with

children and adolescents who have a range of “psychosomatic” disorders such as anorexia nervosa. “Psychosomatic families” were enmeshed, overprotective, rigid; avoided conflict; and used the child’s problems to detract attention from parental. The treatment corrects defensive interactional patterns to enhance separation and autonomy in the child. They demonstrated the impressive impact of structural family therapy on families with younger adolescents who have eating disorders and other psychosomatic reactions. However, the utility of the model with older patients who have bulimia has not been established (58).

Behavioral family therapy and psychoeducation also have been applied to eating disorders and anorexia nervosa. They address risk factors for eating disorders such as parental intrusive, critical, and overcontrolling behavior and low family cohesion (59).

Eisler et al. (60) argue that parallel treatment of the parents and anorexic adolescents is highly effective when there is a high level of maternal criticism. Application of family therapies is effective in bringing about weight gain, but has also increased the level of overt family conflict, which supports the observation that conflict avoidance and denial is a significant characteristic of families of adolescents with eating disorders (61).

FAMILY THERAPY AND ADOLESCENT SUBSTANCE ABUSE

Family therapy with adolescent substance abuse has been described by multidimensional family therapy and MST. Liddle (62) and Liddle and Dakof (63) have applied multidimensional, multicomponent, and multisystemic comprehensive family intervention to substance abusing adolescents. They have investigated the links between changes in parenting and reductions in adolescents’ drug abuse, improving the therapist-adolescent alliance and addressing cultural and gender issues in treatment. Their preliminary findings are supportive of effectiveness of family interventions in comparison with other treatment modalities.

MST (48,49,64) has been applied to treatment of substance abuse in adolescents with very encouraging results. It has been effective in reducing drug use, rearrests, and the number of days in placement.

FAMILY INTERVENTION IN RESIDENTIAL TREATMENT CENTERS

Research has identified the lack of a meaningful conceptual framework guiding intervention with families as the major factor limiting the effectiveness of residential treatment (65). Family intervention in a residential treatment center should be guided by two variables: (1) the state of disintegration of the family unit and (2) the level of

availability of the family as a potential care provider or participant in psychiatric treatment. Based on assessment of these variables, families of patients in a residential treatment center can be divided into four groups: (1) available families, (2) potentially available families, (3) partially available families, and (4) totally unavailable families (32,65).

Available Families

The available family is forced to institutionalize the child after family confrontations at the height of negatively escalated interactions. The family and child are strongly bonded and depend on one another to the point that they cannot live with or without each other. Such families are available for home visits, participation in family sessions, and eventual family reunification.

Potentially Available Families

The potentially available family has lost its immediate ability to care for the child because of a loss of functional capacity in the nuclear or extended family. A history of divorce, remarriage, physical or psychiatric illness, or death should alert the treatment team to the loss of family resources and capacity. The therapeutic task is to recognize the limitations in the functional and caretaking capacity of these families and protect them from any unrealistic and premature demands. The functional capacity of the family should be increased by resolving intergenerational conflicts, improving the functional and economic capacity of the parents, and activating the parents' social networks.

Partially Available Families

The partially available family interacts with the child through erratic telephone calls, occasional visits, or irregular attendance in treatment sessions. A major clinical finding in such families is the extreme nature of parental incapacity in managing life tasks. A realistic treatment strategy is to maintain the family's connection with the child psychologically while making realistic living plans for the child after discharge from the residential treatment center. The family can continue to remain as a resource to the group home or foster family after the child's discharge from the residential treatment center.

Totally Unavailable Families

The totally unavailable family is characterized by loss of contact with the child many years before his or her admission to a residential treatment center. There is usually a

distorted and unrealistic expectation of a potential reunion between the family and the child. Such distorted fantasies should be discussed immediately and continuously throughout residential treatment. It would be helpful if the families could be located early in the course of residential treatment to verify—either in person or by telephone—their inability to take care of the child. This strategy would help resolve some of the child's dormant fantasies and conflicts and facilitate his or her future adaptation to other living possibilities.

RECENT DEVELOPMENTS IN FAMILY THEORY AND THERAPY

In the past decade, the field of family therapy has moved toward more empirically derived measures, such as EE, and away from theoretically driven constructs. There has been a close adherence to the stress-diathesis model (66–68) and the Finnish adoption studies (67), particularly in reference to major mental illnesses. This model recognizes the presence of reasonably convincing evidence for a strong genetic predisposition to a number of major mental disorders, such as schizophrenia, bipolar disorders, and alcoholism, which, in interaction with various intercurrent life events within and outside of the family, can affect the risk for emerging or recurring disorder in a family member. Contemporary family therapy also clearly recognizes the efficacy of psychopharmacology in schizophrenia and depression.

Stress-Diathesis Theory

Stress-diathesis or stress-vulnerability theory was first proposed by Rosenthal in 1970 and further refined by Zubin and Spring (68). Stress-diathesis theory regards the disorder as a product of two sets of variables: (1) vulnerability and (2) stressors. Vulnerability can be the result of genetic and psychobiological factors, although psychological and interpersonal vulnerability can function in a similar fashion. Genetic factors have been studied in schizophrenia, depression, and alcoholism. Stress can be caused by external factors or as a result of stressful psychological mechanisms or interpersonal patterns. The perspective of stress-diathesis theory is that illness is the result of heightened vulnerability and stress, and can be best prevented, managed, and treated by altering both sets of factors. Psychotropic medications function by reducing vulnerability, family interventions focus on lowering interpersonal sources of stress, and enhancing coping and problem-solving capacities.

Finnish Adoption Studies

The Finnish adoption studies (67) have produced data supporting the combined and interconnected role of genetic and familial variables in schizophrenia and other mental disorders. Researchers studied the level of family functioning, adaptability, and organization of adoptive families and dividing them into five groups from "optimally functioning" to "inadequately functioning." Although all families adopted children with comparable genetic vulnerability to schizophrenia, the outcome of the children was significantly correlated with level of family functioning. There were no psychotic or borderline children in the two groups of families with optimal or close to optimal functioning. In contrast, there was a preponderance of schizophrenic and borderline patients in the two groups with the lowest level of functioning. The Finnish study strongly supports the notion that genetic risk can be enhanced or decreased according to the level of functioning and adequacy of the family.

FAMILY VARIABLES IN DEVELOPMENTAL PSYCHOPATHOLOGY; SCHIZOPHRENIA

A significant change has occurred in conceptualizing the family dimension of schizophrenia. The family is viewed as a major resource whose availability to the patient can make a crucial difference in positive outcome. Negative interaction between the patient and family now is seen as largely reactive to the patient's symptoms rather than causative. Blaming family interactions (double blind) or the parents (schizophrenogenic mother) has become obsolete.

Family studies based on the stress-vulnerability model have investigated variables that can differentiate families of schizophrenic patients from families of nonschizophrenic patients. Studies of indicators of risk have focused particularly on three variables: (1) EE, (2) communication deviance, and (3) affective style (69,70).

Expressed Emotion

In 1962, Brown et al. reported that male patients with chronic schizophrenia who had returned to live with their families following psychiatric hospitalization were more prone to rehospitalization than patients who went to other living arrangements (71). He proposed the term *expressed emotion*, a composite variable with the values of high and low, as an index of the family's criticism of and overinvolvement with the patient. EE refers to negative emotional attitude. A number of subsequent British and American studies have indicated that the rate of relapse in schizophrenic and depressed patients in families with high EE is four times higher than that in families with low EE (72). The interventions with families having high EE, with specific goals for reducing familial hostility and over involvement, have provided experimental evidence that a decrease in the level of EE results in a decrease in the

occurrence of relapse (72). Vaughn and Leff (73) have suggested that families who blame the illness rather than the patient for the behaviors typically accompanying psychiatric impairment are likely to be supportive or have low EE. Families with high EE, in contrast, seem more inclined to attribute the causes of deviant behavior to the patient.

Communication Deviance

Wynne and Singer (1963) posed the concept of communication deviance to describe nonschizophrenic patients (74,75). A lack of clarity in communication and disturbances in maintaining attention in the parents of schizophrenic patients in comparison to nonschizophrenic patients. Subsequent studies have indicated that communication deviance is related to the severity of psychopathology in the offspring, although some of the disturbances are nonschizophrenic in nature. Communication deviance may represent a cross-generational shared vulnerability in the parents and children affecting attention, perception, and information processing. Longitudinal studies of communication deviance have shown a high risk for psychopathology in children of parents with high communication deviance, particularly if there is concomitant high EE and negative affective style.

FAMILY CLASSIFICATION AND DIAGNOSIS

Family therapists have described different types of families: undifferentiated, enmeshed, disengaged, and psychosomatic. DSM-IV has rekindled the interest in an empirically based family classification and diagnostic system. A family classification system has been proposed by the family committee of the Group for the Advancement of Psychiatry (GAP) (76). They have proposed a document consistent with DSM-IV to specify diagnostic criteria for family and couple relational disorders. The committee's criteria focus on specific family problems such as sexual or physical abuse, divorce, failure to thrive, and separation anxiety (77).

The Global Assessment of Relational Functioning Scale (GARF) developed by Endicott and Spitzer (76) has been used by the GAP committee to evaluate the level of a family's dysfunction, analogous to the axis V rating of global functioning of the individual DSM-III-R. Other authors have proposed a second classification system of family relational disorders (71,78).

FAMILY INTERVENTION IN PSYCHIATRIC HOSPITALS

The goals of the family-oriented model of inpatient intervention are to prevent rehospitalization, strengthen fragile ties between the family and the patient, and help

the family and patient reach the highest functional level. This approach is psychoeducationally oriented, and emphasizes the rehabilitation of the family for a successful reunion when the patient returns home. Inpatient family intervention focuses on treating the patient's illness while recognizing the importance of family variables. It places the relatively causative biologic factors in perspective with the familial and environmental influences. Medication is considered a natural ally of family intervention (10,79,80).

The multiple functions of the psychiatric hospital in regard to the family include addressing problems that are disturbing the family's homeostasis, assisting other disturbed but resistant family members, and helping the family to regain a "lost," severely dysfunctional family member. The family is considered the most important resource, and as such deserves support and respect rather than criticism and blame (81). The relationship between the family and the psychiatrist should be collaborative on behalf of the patient. A variety of family therapy approaches have been used in treating hospitalized patients. The psychoeducational model of family intervention is most effective for families with a member who has been hospitalized for schizophrenia or an affective disorder.

Sholevar (80) has described an "institutionalization process" by which a dysfunctional family in a crisis situation attempts to extrude a vulnerable adolescent to reestablish homeostasis. A variation of the institutionalization process is a multiple hospitalization syndrome, whereby the family insists on returning the child home prematurely to reinvolve him or her in the family's conflicts. Institutionalization process can be countered through conjoint family therapy evaluation and treatment of the whole family by the hospital staff. The family should be involved in the treatment process before the patient's admission to the hospital.

RESEARCH IN FAMILY THERAPY

Progress in family therapy research has been apparent in the past two decades. The question of whether family therapy is effective has been further refined by examining the effect of specific treatment formats and strategies on specific family problems, individual diagnoses, and mediating therapeutic goals. Studies comparing family therapy with other treatment modalities or combining family therapy with other treatment approaches have focused on the level of responsiveness of different problems to different treatment modalities including family therapy (82).

Studies on child and adolescent disorders, particularly the treatment of conduct disorders and delinquency, have produced encouraging results. PMT (33,41) and FFT (38) have proved very effective. In addition to their favorable effect on targeted behaviors of adolescent patients, they have produced beneficial results with siblings and parents. Research on family intervention with substance abuse has demonstrated effectiveness with subgroups of substance abusers, possibly with younger abusers

still living at home. There has been surprisingly less interest in the efficacy of family therapy in treating patients with eating disorders. The recent findings (60) suggest that nonchronic eating disorders in young patients who live at home with their parents are amenable to family interventions.

There have been a number of studies that clearly define symptomatic behavioral problems in children. The most impressive result has been reduced aggressive behavior in children and adolescents (83). Family therapy was effective in reducing specific problematic child behaviors, as well as in reducing anxiety and depression in the parents, and contributing to parenting skills.

A very promising recent study by Reiss et al. (84) examines the role of genetic and environmental factor in a wide range of family types. The differential impact of shared and nonshared environments on child development can have far-reaching impact on family investigations and treatment in coming decades due to dramatic ongoing changes in family composition.

CONCLUSION

A field of family psychiatry has emerged based on the treatment of disorders with relatively clear genetic components, namely, schizophrenia, depression, and alcoholism. Recent elaboration of stress-diathesis theory has led to new developments in family psychiatry, especially the focus on genetic vulnerability of different family members to stress and on methods for reducing it. Psychoeducational family intervention has been used extensively to enhance family adaptation, without the risk of increasing stresses in the family by stimulating charged conflictual issues.

Family therapy, in collaboration with the broader field of psychiatry, should better define the family variables of different disorders and their responses to single or combined treatment modalities or a particular family therapy approach. Considering the advances made in biologic psychiatry and mapping human genomes, the interactional and psychological correlates of biologic vulnerability and dysfunction present family therapists with an exciting challenge.

6.3 THE CONTINUUM OF CARE AND LOCATION-SPECIFIC INTERVENTIONS

CHAPTER 6.3.1 ■ DESIGNING EMERGENCY PSYCHIATRIC SERVICES FOR CHILDREN AND ADOLESCENTS

JENNIFER F. HAVENS, RUTH S. GERSON, AND MOLLIE MARR

CHALLENGES TO EFFECTIVE PSYCHIATRIC EMERGENCY CARE

Child and adolescent mental health–related emergency has risen steadily over the last 20 years (1) with the percentage of youth emergency department (ED) visits for mental health issues increasing from 4.4% of all visits in 2001 to 7.2% in 2011 (2). A recent study reveals that the number of child psychiatric ED visits for children under age 17 rose from 500,536 discharges in 2006 to 605,208 discharges in 2011, a 21% increase, while the numbers of nonmental health–related ED visits remained stable (3). Strikingly, Torio et al. (3) report large increases in mental health–related ED visits for children aged 1 to 4 (20.6% increase), for children 5 to 9 (31.4% increase), and for children 10 to 14 (36.2% increase). Studies drawing from older data indicate the largest increase in mental health–related ED visits was for nonemergent issues and may reflect difficulty in access to outpatient mental health treatment (1). However, the latest available study reveals significant increases for visits related to suicide and self-injury in all age ranges, including children aged 1 to 9 (3).

Youth mental health ED visits create considerable burden for largely unprepared ED providers, with longer lengths of stay, higher rates of ED boarding, inpatient admissions and transfers, and higher rates of restraints when compared with nonmental health–related visits. These findings have been reported in single-site studies (4–6), in multicenter collaborations (7–9) and in the analysis of large data sets tracking ED utilization (3,10). There is also evidence that the lengths of stay associated with these visits have increased over time (6,10).

Despite the well-covered crisis of psychiatric patients of all ages in EDs across the country (11), the emergency management system has been slow to evolve to address the needs of young patients. The overwhelming majority of youth in psychiatric crisis are managed either in medical EDs or psychiatric EDs designed to serve adults. These settings generally lack access to round-the-clock child mental health clinicians, let alone child and adolescent psychiatrists (12). Medical ED settings lack access to psychiatric nursing staff and the facilities to safely manage suicidal or aggressive patients. The priority for inadequately staffed ED providers in these setting is triage rather than treatment. Frequently young patients are admitted for inpatient care because they require immediate care, which could be provided on an

outpatient basis if appropriate services were available. With the overall constriction in the public and private inpatient care system (13), the need for inpatient admission can be associated with significant delays and boarding in ED settings (4,10,14). All of this translates into alienating and sometimes traumatizing experiences for children and their families and only serves to reinforce the stigma associated with psychiatric illness.

The crisis in the management of psychiatric emergencies in youth must be understood in the broader context of the challenges in the overall children's mental health service system. Persistent reductions in the number of inpatient psychiatric beds as well as the shift in the inpatient model of care to one of brief stabilization has led to youth at higher acuity being managed in the community. The national average length of stay for youth in inpatient care is now 7 days (3); youth are discharged when they are no longer acutely dangerous, not when they are well. Access to intermediate levels of care (partial hospital programs, intensive outpatient programs) is limited and varies significantly across the country. The children's outpatient care continuum has historically been limited in its capacity to provide acute care and access to child and adolescent psychiatry represents a significant national challenge. These system factors have been noted to be associated with increasing mental health visits to ED, particularly nonemergent visits (1,15,16).

Several structural issues contribute to the challenges EDs face in meeting the mental health needs of youth. First overall volumes tend to be low when compared to adult patients so the ED psychiatry workforce is likely to lack child and adolescent competencies. Severe national shortages of child and adolescent psychiatrists also exacerbate this problem. Second, the psychiatric consultation model in EDs significantly impacts reimbursement, particularly when caring for publicly insured patients. Hospital systems have little incentive to support child mental health clinicians in low-volume, low-reimbursement settings (12,15–18).

These challenges have resulted in a system of ED care which commonly fails to meet the needs of youth in mental health crisis. In 2013, suicide was the second leading cause of death in 15 to 24 year olds and the third leading cause of death in 10 to 14 year olds (19). Unintentional injury is the first leading cause of death in youth (19) and there are reasons to believe that the national system of reporting unintentional injury understates the "overall magnitude of fatalities arising from deliberate, self-destructive behaviors" (20). Deliberate self-harm has been clearly established as a risk factor for youth suicide (21) and yet in 2009 only 39% of self-harming youth covered by Medicaid presenting to EDs received a mental health assessment and only 43% received follow-up outpatient care (22).

MODELS OF EFFECTIVE CRISIS INTERVENTION

Across the United States and in Canada, a number of models have been implemented

that address the many challenges to the provision of effective care for young people in psychiatric crisis (18,23,24). Janssens et al. provided a particularly thoughtful and comprehensive overall of both the theoretical and structural underpinning of available crisis intervention models, which have been applied across a broad range of settings, including community and home-based settings, clinics, and EDs. Several have evidence supporting their effectiveness (23,25,26) but it is clear there is a need for more rigorous study in this area (23,27). All of the models require resource allocation to allow for immediate access to child and adolescent mental health clinicians that support children and families through the crisis period; all program models share reductions in inpatient utilization and improvement in quality of care. Several ED models which support after-ED discharge connections have been shown to improve linkage to outpatient services for high-risk patients. These programs are detailed below.

Community-Based Models

Homebuilders and Multisystem Therapy are examples of well-established models that have been adapted to serve children during a psychiatric emergency. Both are evidence-based models centered on intensive community-based care. Initially developed for child welfare populations in order to support family preservation (28,29), the Homebuilders model has been successfully applied in the prevention of psychiatric admissions in children and adolescents (30,31). The New York State Office of Mental Health has invested in the Homebuilders model, now called Home-Based Crisis Intervention, and supports this program throughout New York City. The Home-Based Crisis Intervention provides short-term services (6 to 12 weeks) in the home as well as linkage to outpatient services for youth identified as at-risk for psychiatric hospitalization. In addition to successfully diverting over 90% of young people from psychiatric admission, this model has also been found to successfully manage youth at the same acuity level as patients admitted to inpatient psychiatric services (32).

Multisystemic therapy (MST) has also been adapted for children and adolescents at risk of psychiatric hospitalization. In randomized clinical trials, this MST adaptation was shown to be safe and effective in the management of these at-risk youth (33). Like the Homebuilders model, MST provides home-based services, but the intensity is dependent on the needs of family and is therefore variable. Generally, the length of treatment in MST is longer (average of 4 months) compared to the Homebuilders model. MST is a strength-based model designed to help families identify and leverage resources and strengths to enact change through a combination of family, behavioral, and psychosocial interventions. In order to address the unique needs of families with a child in psychiatric crisis, child and adolescent psychiatrists were added to the treatment team and the development of comprehensive crisis plans

was incorporated in the MST adaptations (33–35). A randomized controlled trial of MST versus hospitalization in patients following a psychiatric emergency showed a 57% reduction in hospitalization for those enrolled in MST (36) as well as a reduction in suicide attempts among youth referred for hospitalization following threats of harm to self or others or suicidal ideation or attempt (37).

Mobile crisis services is another community-based model with a growing evidence base. Mobile crisis teams provide on-site evaluation at the place of crisis (home, school, community) and determine what services the child needs. Services are dependent on what is available in the community or region, but may include referral to a higher level of care, referral and linkage to outpatient services, respite care for parents, or short-term wraparound services. Mobile crisis teams are also used to contact high-risk patients with recent ED visits or hospitalizations who fail to attend scheduled appointments or to facilitate linkage to outpatient or supportive services (38). In Milwaukee, Wisconsin, the ability of mobile crisis teams to facilitate transfers for inpatient treatment and provide access to crisis respite beds has decreased inpatient admissions (39). In New York, a similar program demonstrated a reduction in ED visits and prevented out-of-home placements (39). Further study of the effectiveness of these programs in youth is warranted as the use of this model is expanding; Connecticut has developed a statewide program supported through government funds and New York City has expanded the mobile crisis response model for youth across all five boroughs of the city.

Hospital-Based Models

These models provide hospital-based services on a walk-in basis or as an adjunct to ED visits, often through specialized crisis intervention teams. Frequently, these programs are co-located with other clinical services and thus able to provide rapid access to clinical teams with expertise in crisis management (40). The development of this model represents an evolution in outpatient care to address the growing demand for acute care capabilities and is highly applicable to existing clinical services. One example is the use of specialized teams in outpatient clinics to provide rapid access and intensive case management to patients in crisis, allowing for a briefer ED stay and preventing the hospitalization of those patients who can be safely managed in an outpatient setting. This model requires access to child psychiatric services, and generally works best in an academic setting with trainees. Maimonides Medical Center in Brooklyn, NY has developed an innovative model to actively link local public schools to their outpatient clinic. Schools are able to send students to the clinic for urgent evaluations on a walk-in basis every day of the work week, preventing school referrals to the ED.

Emergency Department-Based Models

ED-based models extend existing emergency services and provide interventions and support beyond the traditional psychiatric consult model. Although there is variability in how the services are integrated and delivered within a given ED, there are three broad approaches currently in use: providing an enhanced evaluation and facilitated referral, delivering therapeutic interventions during the ED visit, and supporting dedicated psychiatric staff within the ED.

In the enhanced evaluation and referral model ED staff provide facilitated referral to outpatient services, create a verbal contract with the patient, review expectations, provide crisis phone support, and call families to remind them of upcoming appointments and to facilitate connection with these services (23,41). The enhanced evaluation and referral model and the therapeutic intervention model have been evaluated with high-risk patients, typically patients who were seen in the ED for suicidal ideation or following self-inflicted injury, and have shown some promise. One example of the therapeutic intervention model is family-based crisis intervention. The goal of the family-based crisis intervention is to help the child and parents to reframe the crisis, communicate more effectively, identify ways to establish and maintain safety, and address attitudes about engaging in mental health care (42,43). The therapeutic approaches to achieve these goals vary, but may include brief family systems therapy, cognitive-behavioral therapy, or a combination of therapeutic techniques. In one study, staff provided linkage calls to support families and increase compliance with scheduled outpatient appointments (43). This study, as well as others, found improved linkage and greater compliance with outpatient referrals following the use of ED-based therapeutic interventions (42,43).

The Child Guidance Model (44) is an example of a specialized team available to provide immediate psychiatric services within the ED. The team evaluates children with psychiatric complaints and includes a psychiatric social worker and a child psychiatrist. The psychiatric social worker is available to perform psychiatric assessments and provide comprehensive disposition planning in the ED 24 hours a day. A study of this model found a reduction in the length of stay in the ED as well as a reduction in costs (44). Additional studies of specialized child psychiatric teams in the ED providing evaluation and disposition planning found reductions in inpatient admissions and return visits to the ED (27).

Specialty Psychiatric Emergency Programs

The New York State Comprehensive Psychiatric Emergency Program (CPEP) model mandates a comprehensive range of services, including comprehensive psychiatric and psychosocial evaluation, extended observation beds for brief stabilization (up to 72 hours), immediate access to outpatient clinic services though an interim crisis clinic and mobile crisis services. This model was implemented in New York State in

the late 1980s and provided the first statewide model of the implementation of regulated and organized emergency psychiatric services (45). The first dedicated Children's Comprehensive Psychiatric Emergency Program (C-CPEP) in New York State (at New York Presbyterian Hospital) reduced inpatient psychiatric admissions in Northern Manhattan from 35% to under 10%, but was closed when inadequate volume and reimbursement did not support program costs, reflecting to the reimbursement challenges inherent in operating dedicated psychiatric units for youth. These types of programs, which are becoming more common for adults across the country, require considerable capital investment and institutional commitment to develop and implement as they are expensive to build and operate and require a critical mass of child psychiatry staffing. The second dedicated C-CPEP in New York State (at Bellevue Hospital Center) serves both Bellevue Hospital and as well as several other public hospitals in the New York City Health and Hospitals Corporation that lack child and adolescent inpatient services. The C-CPEP includes six extended observation beds staffed 24 hours a day/7 days a week with child psychiatry, child psychiatric nursing and social work. The service also provides Interim Crisis Clinic services, which follow patients discharged from the C-CPEP for up to three visits. This combination of immediate access to outpatient follow-up and brief stabilization prevents longer admissions except when necessary; only 20% of children and adolescents evaluated in Bellevue C-CPEP are admitted to inpatient psychiatry units. A similar specialized program opened at the Institute of Living in Hartford, Connecticut (the CARES Unit) in 2009, in response to the dramatic increase in young people in psychiatric crisis in medical EDs in that state. Recently, another brief stabilization unit opened in Geneva Switzerland, at the Children's Hospital of Geneva Hospitals.

ROLE OF QUALITY STANDARDS IN IMPROVING PSYCHIATRIC EMERGENCY CARE

The range and variety of psychiatric emergency services for youth across the country reflect the lack of quality standards as well as significant challenges to fiscal sustainability (15,16,24). One significant barrier to the broader implementation of community-based models is the requirement for ongoing public funding to support program costs. Despite the clear cost-savings from hospital diversions, these types of services are generally not covered by insurance providers. Strategic collaboration with insurers (both commercial and public) is essential to the successful dissemination of these program models, which have clear potential to reduce inpatient utilization. More rigorous study of the cost-effectiveness of commonly used community-based models (home-based crisis intervention, mobile crisis services) would be helpful to support the uptake of these services by private insurers.

Increasingly, public sector funding also supports mental health services delivered

to youth in EDs. The overall share of ED visits supported by Medicaid increased from 45% in 2006 to 53% in 2011 (3). This represents an opportunity to leverage the increasing focus on quality and outcome demonstrated in public sector funding streams to develop nationwide standards for children's psychiatric emergency care. This would serve to reduce the variability and improve the quality of services children receive; improve the linkage of high-risk youth to aftercare services and potentially change the trajectory of completed adolescent suicide, now trending in the wrong direction (19).

Canada has taken a step in this direction, with the development and implementation of an ED care pathway for youth mental health visits (46). This pathway dictates structured screening to be implemented by all ED staff to identify high-risk youth, the 24/7 availability of a specialized child and adolescent clinician to evaluate identified patients and structured collaboration with community-based providers to provide facilitated and immediate access for high-risk patients and rapid access for lower-risk patients requiring follow-up. This pathway has also standardized documentation and transfer of treatment information across care providers. Evaluation of the pathway is underway.

In the United States, extensive advocacy will be necessary on a national level to force the development of standards of care and insure adequate reimbursement for pediatric psychiatric emergency care. Following the path of emergency medicine and accrediting and designating centers of child and adolescent psychiatric emergency care is one approach to improving the accessibility of quality care, facilitating patient transfer and linkage, and creating an infrastructure for innovation, research, and training. As developed by the Illinois Emergency Medical Services for Children program, the pediatric emergency medicine facility designation process in the area of pediatric trauma care led to the development of statewide standards and protocols for the provision of emergency medical care to children and engaged providers across service systems including EMS, schools, rehabilitation centers, poison control centers, and hospitals (47). They have been able to leverage the partnerships formed as part of the designation process to advance disaster preparedness, develop a surveillance system, implement and evaluate system-wide quality improvement projects, and address workforce, equipment, or space shortages. Their designation process encompasses three levels of pediatric trauma care, based on the ability of hospitals to provide optimal pediatric care. EMS diversion protocols are used to decrease ambulance transport to hospital without adequate care capacity. Hospitals must have transfer guidelines in place, especially those centers unable to provide specialized pediatric care. The system facilitates medically necessary pediatric transfers both through the requirement of current policies and interagency agreements, but also by maintaining up-to-date information on the location and availability of transportation teams, specialized centers of care, and pediatric beds.

Given the workforce constraints in child and adolescent psychiatry, specialization

and designation are essential to support centralized settings serving regional areas with adequate staffing and space to manage child and adolescent psychiatric emergencies. The C-CPEP at Bellevue Hospital Center/NYU provides such a model, with the C-CPEP supporting the transfer of patients across New York City from both the public and private sector hospitals. This model is feasible in a well-developed child and adolescent psychiatry department with an adequate psychiatry work force to provide 24/7 coverage and where there is institutional commitment to meeting the mental health needs of children and adolescents. Children's hospitals, who across the country struggle with increasing ED mental health volumes, represent a natural setting for the expansion of the specialized model. Accrediting and designating centers of child and adolescent psychiatric emergency care is an important next step in assuring access to high-quality care, and providing the infrastructure to evaluate and improve the existing service system and support the development of new models of care.

MANAGEMENT PRINCIPLES AND PRACTICE

Safety in the ED

Setting

The first priority of any emergency psychiatric assessment of a child or adolescent is safety. The patient (and others) must be safe in the ED itself, which may be difficult due to space constraints and the staffing challenges described above. Despite these challenges, children and adolescents presenting to the ED in psychiatric crisis should be kept in safe and quiet areas of the ED, both for the evaluation and while awaiting evaluation, transfer or discharge. Particularly for agitated youth or those who present to the ED for self-injury or aggression, the physical space is key to maintaining safety without requiring restraint or seclusion. The area should be free from items that can be utilized for self-harm or to harm others (such as sharps, cords, or IV poles); should allow for continuous observation of the patient by staff (while still providing privacy); and should have a minimum of bright lights, beeping monitors, and other irritations to decrease risk of overstimulation. Ideally the patient will be made comfortable with a place to lie or sit down and given access to food or drink, particularly if there will be a delay before evaluation will commence. Staff should introduce themselves and provide clear expectations as to the procedure for evaluation, the wait time, the rules of the ED, and the interventions and consequences that will be given should the child become agitated, aggressive, or destructive. These steps will reduce, but not eliminate, the risk of a child or adolescent becoming agitated. ED staff need to be trained in engaging, calming and de-escalating the patient, and sufficient additional trained personnel should be available if needed to provide containment, medication, or restraint for acutely dangerous behavior.

Protocols and response plans should be designed, in compliance with federal, state, local, and hospital regulations, for response to an agitated child or adolescent, and when and how medication or restraint will be utilized. Staff should be familiar with these protocols, and with how to call other staff for support, where to find and how to utilize restraints safely.

Staffing

Children and adolescents are, in general, extremely sensitive to the tone and approach of the adults they meet. In the ED setting, front-line staff who feel comfortable with children and who can maintain a calm, respectful tone will often be able to diffuse even very tense or hostile situations. The initial triage or preliminary assessment of a youth in the ED is key, particularly if there will be a delay before the full clinical evaluation commences. The initial triage can identify risk of medical comorbidity or complications (such as cases of suicidal youth who have overdosed, or intoxicated youth), and any information needed to respond safely in cases of agitation or medical emergency (such as vital signs, allergies, medications prescribed, medical illnesses, and history of abuse or trauma if possible). Structured screening tools such as the Columbia Suicide Severity Rating Scale (C-SSRS) (48), the Ask Suicide-Screening Questions (ASQ) (49), or the Suicide Assessment Five-Step Evaluation and Triage (SAFE-T) (50) can be useful as part of the initial triage to assist in or supplement the assessment of suicidality. If youth are identified to be at immediate risk for self-harm, suicide or harm to others, staff must be made available for continuous observation; ideally, continuous or 1:1 observation should not be done by uniformed officers, which can frighten young children and risks agitating adolescents indisposed to authority figures.

Many EDs lack trained clinical staff to provide psychiatric evaluation and risk assessment for the growing number of youth in psychiatric crisis passing through their doors. This deficit leaves youth vulnerable to the acute and chronic dangers of untreated mental illness, and EDs potentially liable for negative outcomes. The ideal ED assessment of a child will include a child psychiatrist (or a child psychologist in concert with a pediatrician or psychiatrist) and a psychiatric social worker, if not leading the direct assessment then providing consultation and direction to the clinical team.

COMPREHENSIVE ASSESSMENT OF YOUTH IN PSYCHIATRIC CRISIS

The psychiatric evaluation of a child or adolescent in the ED should be guided by three main priorities: assessing safety, identifying, and addressing both medical and social/systemic causes of behavioral disturbance, and providing a therapeutic initial

intervention.

Risk Assessment

Assessing safety of a child or adolescent in psychiatric crisis requires determining acuity and imminence of risk, to ascertain whether a youth with chronic risk factors (such as history of harm to self or others, abuse history, family history of suicide, chronic psychosocial stressors, or substance abuse, among others) can be stabilized sufficiently for safe discharge or requires inpatient hospitalization. Acute risk and protective factors in the mental status, information from available collateral, prior and recent behaviors, engagement with community supports or treatment, and the response to the therapeutic interview and initial treatment will inform the determination of risk (Table 6.3.1.1).

TABLE 6.3.1.1

RISK AND PROTECTIVE FACTORS IN THE CHILD PSYCHIATRIC EVALUATION

	Risk Factors	Protective Factors
Mental status examination	Agitation, paranoid psychosis, insomnia, or anhedonia Refusal to speak or engage, or superficial engagement with interview Currently homicidal or suicidal Unable to talk about the acute events or precipitants Guilt or shame, particularly around recent disclosure of family or sexual abuse Positive expectancies around death (relief of suffering or burdensomeness, joining deceased family members)	Future-oriented (hopeful or curious) Emotionally appropriate when talking about stressors, but able to maintain composure Broad, congruent, and reactive affect No currently suicidal or homicidal ideation (or contingently suicidal, such as, suicidal if made to attend school) No suicidal or homicidal intent or plan
Information from collateral	No available collateral Collateral expresses significant safety concerns Collateral (e.g., parent/guardian) unconcerned despite severe symptoms or acute presentation	Collateral who knows child well understands significance of child's presenting thoughts or behaviors but does not have acute safety concerns
Prior and recent dangerous behaviors	Recent high-lethality suicidal attempt or behavior, escalating suicidal or self-injurious behaviors, or severe aggression Researching death or violent means Longstanding or escalating nonsuicidal self-injurious behavior Believed suicidal behavior would be fatal (regardless of true lethality) Access to sharps, weapons, pills, or other lethal means	Self-aborted attempt to hurt self, called for help, or threatened self-harm or suicide in presence of others Impulsive, low-lethality suicide attempt Minor aggression or property destruction without true intent to harm others High supervision, no access to dangerous objects or lethal means
Engagement	No outpatient treatment or refusal to	Good alliance with outpatient providers

with supports or treatment	attend treatment Poor social supports Limited interest in school, friends, family Recent suicide in peer group, or family history of suicide	Connected to staff and peers at school Supportive family
Response to therapeutic interview and treatment	Does not respond to therapeutic support, remains agitated/suicidal/paranoid/etc. Refuses to engage with therapeutic interview	Responds to therapeutic support and/or medication for psychosis, mania, impulsivity secondary to ADHD, or other acute symptoms Child has successfully coped with similar stressors in the past

Evaluating and Addressing Medical and Psychosocial Causes of Behavioral Disturbance

The second priority of the emergency psychiatric evaluation of a child or adolescent is to determine whether the behavioral disturbance or symptoms are due primarily to psychiatric illness, or a manifestation of either medical illness or social/systemic pathology.

While most children are healthy, a variety of medical illness can masquerade as psychiatric symptoms. While most of these medical illnesses in isolation are rare, together they are a significant (though often missed) cause of psychiatric presentations to the ED. Infections (particularly tropical diseases and encephalitis), neoplasms (both brain tumors and paraneoplastic syndromes), seizures (including temporal lobe and absence seizures), autoimmune diseases (including autoimmune encephalitis as well as systemic autoimmune disorders), and head trauma can present with hallucinations, behavioral dysregulation, and other mental status changes. Undiagnosed genetic syndromes, metabolic disorders, and porphyria can manifest with psychosis or behavioral changes, while youth with undiagnosed sickle cell disease can be dismissed as drug-seekers. Delirium due to drug intoxication, self-poisoning (including accidental ingestions, suicide attempts, or substance misuse), or toxicity from psychotherapeutic agents such as lithium may be missed by parents or medical providers, particularly in adolescents with a history of psychosis or conduct problems. Symptoms that are concerning for possible medical etiology include:

- atypical onset or clustering of psychiatric symptoms (such as acute onset of psychosis in a child with no prior psychiatric history)
- abnormal vital signs
- waxing and waning mental status
- clouding of consciousness
- disorientation
- memory impairment

Medical illness can also complicate treatment of psychiatric illness, due to the frequency of comorbidity and the adverse effects of psychiatric medications. All

children and adolescents presenting to the psychiatric emergency room should undergo medical clearance, and if a medical etiology or comorbidity is suspected, an appropriate medical workup should be completed. This may include a full physical examination; monitoring of serial vital signs; diagnostic studies including laboratory work (chemistries including glucose and electrolytes, complete blood count with differential, thyroid tests, liver function tests, urine drug screen, serum drug levels if applicable, blood alcohol level if applicable, and cerebrospinal fluid tests if encephalitis is suspected); an electrocardiogram; and if seizures or brain neoplasm are suspected, brain imaging and electroencephalogram (Table 6.3.1.2).

Children with acute medical illness or significant medical comorbidity (such as injury due to suicide attempt, severe intoxication or withdrawal, or drug toxicity) will benefit from medical admission for stabilization prior to psychiatric hospitalization.

When acute or severe medical illness is not present, the ED clinician should also remember that minor physical ailments such as ear infections, hunger, fatigue, headaches, constipation, tooth aches, and the normal developmental changes of puberty can all trigger behavioral disturbances in children. Children with communication difficulties, such as young children and youth with intellectual or developmental disabilities such as autism, can be particularly vulnerable to acting out in response to physical discomfort.

TABLE 6.3.1.2

COMMON MEDICAL CAUSES OF PSYCHIATRIC DISTURBANCE IN CHILDREN AND ADOLESCENTS

Fever
Nonconvulsive status epilepticus
Temporal lobe seizures
Absence seizure
Encephalitis
Cerebral systemic lupus erythematosus
Childhood confusional migraine
Head trauma or postconcussive syndrome
Porphyria
Sickle cell disease
Substance intoxication
Withdrawal from illicit substances
Anticholinergic delirium
Steroid psychosis or steroid-induced mania
Central nervous system neoplasm or other occult malignancy
Medication adverse effects such as akathisia from risperidone or irritability from levetiracetam

Psychosocial crisis can also trigger acting out in children and adolescents, and even classically psychiatric symptoms such as hallucinations or anxiety can be engendered by acute stress such as domestic violence, parental mental illness, or abuse. The clinician should be observant, during the course of the therapeutic interview, for signs of distress or pathology in the family or social system. If the

child is the “identified patient” while the true cause of distress is in the family or social context, treating the child alone risks giving the child the message that the problem lies in him, not in the abuse, neglect, or other toxic context in which he finds himself. Even if the child has true psychiatric illness, the presenting issue may be family conflict, parental stress or systems failure that worsen the child’s symptoms or hobble the caregivers’ ability to manage them. Divorce, parental illness, loss of a grandparent or other secondary caretaker, or even summer vacation (with the loss of structure and routine of school) can hinder a parent’s ability to contain a behaviorally difficult child. Removal from parents by child protective services can worsen symptoms of anxiety, depression, or aggression, while placing the child with a foster parent who does not know what triggers or soothes the child. Such situations are common precipitants for an ED visit, yet the crises here are not psychiatric per se. Instead, it is a psychosocial crisis leading to breakdown of the caretaking system. Safe discharge in such cases will depend on identification of caretaking supports as much as provision of psychiatric follow-up.

COMPONENTS OF COMPREHENSIVE EMERGENCY PSYCHIATRIC ASSESSMENT FOR A CHILD OR ADOLESCENT

To stabilize the crisis, the initial interview must be therapeutic in itself. An empathic, open, and curious stance in approaching the child and collateral will help to establish rapport, while direct and clear communication regarding rules and expectations indicate mutual respect. Many agitated, angry or anxious youth can be quickly de-escalated by an adult approaching with empathy and sincere desire to understand what has upset them, rather than with judgment and punishment (Table 6.3.1.3).

The interviews with the child, the parent, and any other collateral sources should ideally be conducted in a quiet, private space free from interruption. If the child or parent is agitated, the clinician should solicit other staff to remain nearby, and should sit between the patient/parent and the door to allow unhindered escape from the room if the patient/parent becomes violent. The child and parent should each be interviewed alone, and in general it is best to interview adolescent patients before their parents or guardians, to demonstrate respect and build rapport with the patient.

TABLE 6.3.1.3

COMPONENTS OF A COMPREHENSIVE ASSESSMENT

Components
Identifying information
Chief complaint
History of present illness
Past psychiatric history
Current medications and medication history
Past medical history

Substance use history
Trauma history
Social history including trauma and child welfare involvement
Developmental and educational history
Family history
Legal history
Mental status examination including cognitive examination when indicated
Medical clearance including physical examination if indicated

Interviewing a Child in Psychiatric Crisis

The first moments of interaction with a child can be rich with information for the diagnostic assessment. Observation of the child's mental status, behavior, attitude toward the parent or accompanying adult and then toward the interviewer, language and social skills, and response to questions all inform preliminary hypotheses about the symptoms or stressors that have precipitated the child's arrival to the ED, and facilitate building rapport and calming agitated or anxious patients.

The interview with the child or adolescent should focus on understanding their perspective, their experience of their symptoms or the reasons behind their behavior, and what they perceive as triggers or protective factors, while observing their mental status. Open-ended questions will be more effective than a "checklist" approach. Specific questions must be asked about suicidal and homicidal ideation, with the recognition that children and adolescents often minimize such acute symptoms once in the ED for fear of being hospitalized or upsetting parents. Asking about suicidal and homicidal ideation at different points in the interview, with phrasing that echoes the child's own words, may be more effective in getting an honest response. Questions about hallucinations and delusions should also be approached directly but phrased carefully, as young children and youth with intellectual or developmental disabilities may misinterpret the questions and give false-positive responses, while those youth who are truly experiencing psychosis may deny such symptoms due to paranoia and anxiety. Finally, the clinician should also observe carefully and query directly for the presence of internalizing symptoms such as depression, anxiety, and trauma-related symptoms, as these are often missed or underreported by parents and other adults (51). If children are very young, have limited expressive language (such as those with autism or intellectual disability [ID]), or are severely uncooperative, the clinician should still attempt a thorough mental status examination using parallel or reciprocal play and observation. The clinician can observe the child's interactions with others, ability to follow commands and express needs (though words or gestures), fine and gross motor skills, hyperactivity, distractibility, frustration tolerance, and attachment to (or fear of) the parent or guardian. Even if the child cannot voice what is wrong, the clinician's observations will nonetheless inform diagnosis, risk assessment and treatment recommendations.

Informants

Thorough assessment of a child in psychiatric crisis requires more information than can be obtained from the patient alone. Collateral from the parent, guardian, and/or other accompanying adult is crucial to understanding the facts of the situation that the child cannot give due to cognitive or emotional immaturity. Other informants will also provide critical information about the child's functioning at home and at school, medical issues and history, prior psychiatric treatment, developmental history, substance use, family history, legal history, social history including trauma exposure, academic history, and current stressors.

The most important collateral information will be obtained from the parent, guardian, foster parent, or other caregiver. This can be complicated, however, as parents and other caregivers whose child is in the ED are often exhausted, frightened, or distraught about the child's illness or behaviors. They may be upset about missing work or afraid about paying the ED or ambulance bill, confused about the nature or source of the child's symptoms, or angry about the child's risky or oppositional behaviors or about the delays in the ED evaluation. Approaching the caregiver with the same empathic, therapeutic stance that is used for the patient can help the parent to calm down and articulate their fears and frustrations. Calming the parent or caregiver will also reduce the child's anxiety or agitation. When the clinician empathizes with how difficult it is to bear a child's illness, to access treatment or services, or to wait for evaluation in the ED, it can also help the parent to be more open to understanding the child's perspective, changing their own parenting behaviors, or in obtaining treatment.

When the child is brought to the ED by someone other than their parent (such as EMS, police, school staff, or child welfare workers), the parent should be contacted as quickly as possible to provide consent for and to participate in the evaluation of the child (52). If the parent or guardian cannot be reached, most state regulations on emergency services allow clinicians to initiate evaluation and treatment of the child without parental consent in cases of truly life-threatening emergencies. In situations that are not immediately life-threatening, staff should make reasonable efforts to contact the parent, and should document these attempts in the medical record, before providing treatment. If the evaluation or treatment must be started before parental consent is obtained, staff should continue to endeavor to reach the parent. If an adolescent insists that parents not be contacted, the clinician should comply with state and local laws regarding adolescents' rights to seek mental health care without parental consent or notification. While many states do allow adolescents to access such care without their parents' knowledge, in general youth should be encouraged to include their parents in the evaluation and treatment, and often the support and facilitation of the ED clinician can produce a rapprochement between the parent and child.

In addition to the parent or guardian, other collateral contacts can provide information that is crucial to the diagnostic evaluation and risk assessment. Adolescents often disclose things to counselors, teachers, therapists, or psychiatrists that they have kept hidden from their parent or guardian. Even if the youth is very open with their parent, teachers, and guidance counselors may be aware of behaviors or social or academic issues at school and can evaluate the child's cognitive abilities and social skills. The pediatrician or case worker can provide an assessment of the family's strengths and vulnerabilities, the child's developmental progression, and any medical issues, issues with compliance, or concerns about abuse or neglect. The parent should provide consent before any of these individuals are contacted, however in potentially life-threatening situations such as concern for child abuse or suicidality, the safety of the child outweighs the risks of breaching confidentiality. Most states allow for exception to confidentiality rules to ensure the safety of the patient, allowing ED clinicians to have contact with outside individuals and providers in emergency situations (52).

After collecting information from the patient and necessary collaterals, the ED clinician must integrate the perspectives provided into a cohesive formulation. The ED clinician will often find that descriptions of symptoms or behaviors (or even awareness of their existence) and explanations for and interpretations of such will vary widely between informants. Parents and other adults often miss or underestimate the severity of internalizing symptoms and over-estimate externalizing behaviors. Parents may be unaware of substance use, stressors at school, or the impact of family stress (such as domestic violence or parental illness) on the child's mental state. Differences in reporting can also stem from real differences in the child's functioning or behavior in different settings, such as at home versus at school. Discrepancies in reporting can also reflect secret or hidden pathology in the family or system, such as abuse, parental mental illness, or substance use. The clinician may never be certain where the truth lies between discrepant reports, but understanding these sources of variance is necessary for the creation of an effective formulation and treatment plan.

MANAGING THE AGITATED PATIENT

Aggression and agitation are among the most common reasons youth are brought to the ED. Calming agitated youth is key to ensuring that the ED evaluation and treatment is therapeutic, not traumatizing. One in fifteen youth in the ED for psychiatric complaints are restrained due to agitated, aggressive, or otherwise unsafe behavior (53). Restraints can be frightening and confusing for a child or adolescent; afterward they often report feeling afraid of and angry at staff, and their perception of time can become skewed such that they perceive themselves as having been in restraints for much longer than actually occurred (54). Many restraints in the ED can be avoided through proactive steps to prevent agitation and avoid escalation and

through judicious use of psychopharmacology.

Most agitation in the ED is, on some level, preventable. Irritants such as excessive noise, overcrowding, lack of privacy, long and unpredictable wait times, uncertainty about process and outcome, and an overall tense atmosphere can agitate even normally quiet children (or adults). This is particularly problematic for youth who are vulnerable to agitation, particularly those with impulse control problems, trauma history, autism, or psychosis. ED staff should be vigilant in observing for early signs of agitation in these youth. Children and adolescents who are prone to agitation or violence can escalate quickly, but even they generally manifest small shifts in their tone or mannerisms, their way of interacting with their family or accompanying adults, or their body language (such as pacing or engaging in repetitive or self-stimulating behaviors). De-escalation strategies are most effective if used in response to these early signs of distress. First, the child should be moved to a safe and quiet area, away from other patients. For children for whom the parent or accompanying adult is a comfort, they should be rejoined with the adult; for those for whom the adult is an agitating or distressing presence (such as police officers or an anxious or critical parent), the adult and child should be separated. If the parent's anger, anxiety or agitation is triggering the child, staff should speak separately with the parent to understand and address their concern, be it about the time or cost of the ED evaluation, feeling blamed or responsible for their child's illness, concern about stigma or fear of their child being "taken away."

To avoid the agitated child feeling threatened or overstimulated, one member of the staff should serve as point-person for the patient, while others are close by for support. Staff can offer the child food, water, juice, or basic entertainment (such as TV) to calm and distract them. Offering choices (such as water or juice, or which TV channel) can help the child feel respected and in control, and thus help them to calm down. The staff member should approach the child with open-ended, nondirective questions to understand the child's complaint or concern and encourage them to express their needs. If the child is able to verbalize their concerns, these should be met with empathy and validation. Often children who become agitated are worried about the ED process, the possibility of hospitalization, or their parents' reaction. Others may be paranoid, may have experienced trauma or abuse that has led to hyperreactivity to perceived threat, or may be hungry or in pain. As the child is able to express their concerns and make incremental steps to calm down, staff should praise these positive efforts and make it clear that staff intend to help, not to give judgment or punishment. At the same time, the youth must understand that violence will not be tolerated and that staff will work to ensure everyone is safe.

The child's response to these interventions will inform next steps as well as contribute to the preliminary differential diagnosis. Agitation or violent behavior in the ED is usually multifactorial. Youth can be vulnerable to agitation due to a range of symptoms and psychosocial factors. Some are chronically irritable, due to

temperament, severe anxiety, or upbringing in chaotic, neglectful or violence-prone families or communities. Others have poor frustration tolerance due to cognitive deficits, developmental delays, autism, or upbringing (including exposure to abuse), or misinterpret neutral or benign interactions as hostile or aggressive. Youth who are impulsive, due to ADHD, hypomania, or conduct disorder, are also at risk for aggressive behavior. All of these youth may be able to respond to verbal de-escalation, particularly with validation, positive reinforcement of safe behavior, and coaching around collaborative strategies for solving conflicts or ameliorating anxieties. Youth who are psychotic, manic, delirious, or disorganized, may be less responsive to calming techniques and require medication.

If the patient is not responsive to verbal de-escalation and continues to escalate, oral medications should be offered. Oral medication should always be offered before injectable (IM) medication. Many youth are afraid of needles and may become more violent when approached with an injection. Many youth who refuse an oral medication initially will accept it if given the choice between an oral or injectable dose. Offering such a choice allows the child an opportunity to demonstrate self-control and avoids the potentially traumatic experience of restraint and injectable medication.

The preliminary differential diagnosis inferred from the mental status examination and any information gleaned from the initial interviews, as well as any information about the child's prior diagnoses and current medications (if any), will inform the choice of medication. For example, an adolescent with schizophrenia or bipolar disorder already on medication may require an additional dose of their antipsychotic medication. A young child with a history of abuse who is agitated after separation from the parent, who has never been on medication, may be more safely calmed with diphenhydramine. An adolescent with severe anxiety may benefit from a small dose of a benzodiazepine, while for a child with autism or ID, such medications can cause disinhibition and paradoxical agitation. Medications should be chosen carefully and dosed cautiously, to avoid adverse effects. Youth who are antipsychotic naïve, particularly those who are not psychotic or manic, can be at particularly high risk for adverse effects when given high-potency neuroleptics for agitation.

If all de-escalation techniques have failed, and the child has either refused or not responded to oral medication and is engaging in violent or acutely dangerous behavior, an injectable medication may be required. Depending on the nature of the patient's illness, the medication may be pharmacologic management of the patient's underlying illness in the same way that oral medications would be used (e.g., a dose of antipsychotic given intramuscularly in an agitated psychotic patient who has refused his oral antipsychotic). Alternatively, acute chemical restraint may be required. Given the risks of polypharmacy in children, the medication used should be chosen carefully based on the child's age, size, standing medications (or other recent medication administration), medical conditions, current symptoms, and (if known) the

psychological cause of their agitation. For young children, those who are medication naïve, and those whose agitation and aggression are based in trauma or extremely poor self-regulation skills, diphenhydramine (Benadryl) IM may be preferred as it is sedating and generally well tolerated. High or repeat doses of diphenhydramine can cause disinhibition, confusion or delirium, so the total daily dose must be monitored. If diphenhydramine is not tolerated or is insufficient, a sedating lower-potency antipsychotic such as chlorpromazine (Thorazine) may be safe and effective, though higher doses can risk orthostatic hypotension and tachyarrhythmias. Adolescents who are agitated due to anxiety may respond well to IM benzodiazepines such as lorazepam (Ativan), while young children and those with autism or developmental disabilities are more likely to experience paradoxical agitation or disinhibition if given benzodiazepines. Adolescents who are agitated due to paranoid psychosis or mania will likely require haloperidol or another high-potency antipsychotic. If high-potency antipsychotics are administered the patient should concurrently be given diphenhydramine or benztropine (Cogentin) to reduce the risk for dystonic side effects. Adding diphenhydramine to haloperidol (or to a low-potency antipsychotic such as chlorpromazine) can also enhance the sedating effect for youth who are extremely agitated or aggressive. Dosing of injectable medications should generally be half of the oral dose that would be used, and caution should be used before considering typical adult doses of medications for chemical restraint in youth.

In most cases of chemical restraint, a physical hold, restraint or seclusion is also required for the safety of the child and those around him. State and local governmental and oversight agencies, hospital policies, and the regulatory standards set by the Center for Medicare and Medicaid Services and The Joint Commission dictate for which patients a hold, restraint or seclusion is appropriate (55). Physical hold, restraint or seclusion should only be used to prevent serious harm to self or others, but a different intervention will be most therapeutic for the child based on their individual history. Seclusion may be safer for youth with a history of abuse, whereas restraint could be experienced as re-traumatizing. For a young child, a therapeutic hold may be more appropriate, while seclusion could be deeply frightening for the child. The patient in hold, restraint or seclusion should be monitored continuously by staff, and the physician must monitor the child's physical health and comfort and ensure the child is safe. Staff should also explain to the child the reason for the restraint or seclusion and what the child must do to demonstrate that he is safe to be released. The child should be removed from restraint as soon as he is in control, and restraint should never exceed the limits mandated by The Joint Commission, the Health Care Financing Administration, and individual hospital policies. Once the child is released from restraints, the clinician should meet with the child for a debriefing discussion to help the patient to process what has happened and understand the reason for restraint and how to prevent similar incidents in the future. For youth prone to agitation or aggression, the debriefing is an important therapeutic

opportunity for the youth to understand his own feelings and behavior with an adult who is empathic and validating, not judgmental or punitive.

SPECIFIC PSYCHIATRIC EMERGENCIES IN YOUTH

Suicidal and Self-Injurious Behavior

Risk Assessment

When children and adolescents present to the ED after an episode of self-harm, it can be difficult to determine whether the self-injury was deliberate or accidental, and whether it was made with suicidal intent. The child's self-report of suicidal intent and current suicidal thinking is not sufficient to determine risk for future suicidal behavior. Many patients who go on to attempt suicide deny suicidal thoughts to clinicians but speak to family members about their suicidal thoughts (56), and in an ED especially youth may be motivated to minimize their suicidal thoughts or intent due to fear of hospitalization, upsetting family members, or other perceived consequences. Thus the ED clinician should speak with collateral regarding any recent statements of suicidal ideation or intent, hopelessness, anhedonia, or command auditory hallucinations to harm self; history of prior suicide attempts or ideation, substance use, prior psychiatric diagnoses (depression, substance use, bipolar disorder, and conduct disorders confer increased risk for suicide); family history of suicide or recent suicide in the peer group or media; and access to firearms or other dangerous means. The context of the self-harm or suicide attempt is also important, and both the collateral and the patient should be asked whether the patient wrote a suicide note or made other preparation for death, made efforts to hide their attempt or ensure no one would find or help them, or if they experienced regret or ambivalence after the attempt and immediately called for help. The ED clinician should ask the child about their intentions and planning leading up the attempt, the anticipated lethality (or if the child thoughts someone would discover or rescue them), and triggers for suicidal thoughts including perceived burdensomeness, social isolation, or rejection (57). During this discussion the clinician should be vigilant for cues in the mental status examination that suggest acute risk, such as hopelessness, perceived worthlessness, preoccupation with death, severe depression, and command hallucinations, as these are more difficult for a child to hide or minimize. Affective disengagement or superficial discussion of serious suicidal behavior is also a red flag that the patient is minimizing the severity of risk.

If the child or adolescent denies suicidal intent and collateral sources corroborate this, it is important not to dismiss self-injurious behaviors as attention-seeking or reflecting personality disorder, as might be done in adult patients. Repeated self-injury in youth is a risk factor for later suicide attempts (21) and youth who cut

themselves or engage in other self-harming behaviors without suicidal intent (or with ambivalent intent) can inadvertently hurt themselves, due to misjudgment or impulsivity. Other youth may engage in clearly nonfatal behaviors (such as superficial self-cutting, or taking double the recommended dose of a vitamin or over-the-counter painkiller) but with suicidal intent; clinicians should not dismiss these youth as “dramatic” or attention-seeking as if their intent is to die, their next attempt may be of higher lethality.

Management

Inpatient hospitalization is likely necessary if the patient is at high risk, such as (but not limited to) those youth with:

- persistent, intense suicidal ideation or intent
- serious, high-lethality suicidal behavior or attempt (regardless of whether current or persistent suicidal thoughts are endorsed)
- suicidal thinking or behavior in the context of command auditory hallucinations to harm self, severe depression, hopelessness, self-blame, severe social isolation, or poor supports (family rejection or abuse, no outpatient treatment)
- suicidal thinking or behavior in the context of profound psychosocial stressor, such as recent sexual trauma or disclosure of abuse, severe bullying, or relationship loss

If the patient does not require hospitalization, a safety plan should still be determined for discharge. This includes not only connection with treatment providers (with prompt follow-up, ideally within a week, for reassessment and stabilization), but also identification of supports and coping strategies if suicidal thoughts return, and the triggers for suicidal thoughts. A safety plan is also necessary for youth who present with nonsuicidal self-injurious behavior, with the focus being coping with urges to self-harm rather than suicidal thoughts. The clinician should also help the youth to identify the function of the self-harming behaviors, such as relief of numbness or strong negative emotions, attention from peers or family, or release from conflicts or overwhelming stressors. Self-injurious behaviors in youth with anxiety disorders, childhood maltreatment, or autism may function to allow escape from hyperstimulating or otherwise challenging environments (such as a classroom that is too loud or academically too difficult). Identifying the function of self-injurious or parasuicidal behaviors allows the clinician to identify situations that overwhelm a child’s ability to cope or communicate distress and areas where skill-building and support is needed.

Aggression

Risk Assessment

Many youth presenting to the ED for aggression are agitated, irritable, or aggressive on arrival. As noted above, the patient's response to de-escalation techniques over time will inform both diagnosis and risk assessment. Once the patient is calm enough to engage with the interview, the clinician should attempt to understand the aggressive behavior. Aggressive behavior is rarely random and the clinician should endeavor to understand the child's perspective as to the reason for the aggression. Such an approach is therapeutic for the patient and helps to identify specific risk for future aggression. Impulsive, reactive aggression may be triggered by psychological insults such as humiliation or teasing by peers, frustration or rage when limits are set by authority figures, or intense anxiety related to a trauma reminder in a child with PTSD or a change in routine in a youth with autism or ID. "Cold," planned or instrumental aggression may be in response to narcissistic injury, a hostile attribution bias, or a belief (often ingrained by family or peer group) that aggression is an appropriate means to obtain a desired object or assert power. Approaching the child with curiosity and a desire to take his perspective without judgment increases the likelihood that the patient will be honest and forthcoming, and also the patient's response to this approach is revealing. A youth who despite this approach is superficially engaged or insincere, deflects responsibility or minimizes the severity of his behavior, likely has little motivation to change or engage in treatment. Paranoid or disorganized thinking, persistent anger or hostility, and specific homicidal ideation or intent are also indicators of greater risk.

In speaking with collateral sources, the ED clinician should be attentive to different perspectives on the episode, history of severe or escalating violence, evidence of premeditated aggression or homicidal intent, and use of weapons all demonstrate elevated risk. Understanding the context of the aggressive behavior is particularly important for young children and those with autism, ID, or language impairments who may be unable to explicitly identify the trigger for their behavior.

Management

Risk for future violence, and the treatment that may mitigate that risk, depends on the child's underlying psychiatric illness and the nature of the aggressive behavior. Premeditated or instrumental aggression can be seen in youth with conduct disorder or substance use, or in youth with gang involvement or other societal risk factors unrelated to psychiatric illness. Effective treatment of instrumental aggression requires setting clear consequences and promoting prosocial behaviors through programs such as MST, described above. Reactive aggression is more common in youth with mental illness. Treatment for reactive aggression involves identifying and treating the underlying symptoms and deficits in self-regulation that predispose the child to aggression, then identifying triggering situations and teaching coping skills to manage those situations without aggression. Whether such treatment must happen on an inpatient unit or can be safely administered in the community depends on the

nature of the underlying illness, the severity of aggression, and the availability of appropriately intensive community supports and treatment. For patients to be discharged from the ED, the clinician should create a safety plan, similar to that for suicidal behaviors, to identify how the child can cope safely with situations that typically trigger aggression (Table 6.3.1.4).

If the aggressive behavior is not rooted in psychiatric illness and inpatient hospitalization or treatment is unlikely to be helpful, the ED clinician may need to coordinate with parents to identify other supports to contain the youth's behavior, or with law enforcement if the behavior is criminal in nature.

TABLE 6.3.1.4

PSYCHIATRIC DISORDERS AND TREATMENT OF ACUTE AGGRESSION

Illness/Symptom	Treatment Focus
ADHD	Address impulsivity
ODD	Set clear limits, reinforce positive behaviors
Psychosis	Treat command hallucinations/paranoia that are triggering aggression
Mania	Stabilize mania to address impulsivity/irritability
Anxiety or OCD	Identify and address triggers (such as being blocked from completing compulsions)
PTSD	Identify trauma reminders, promote safe coping behaviors
Autism	Promote verbal problem solving and other coping behaviors
Conduct disorder	Set clear consequences for antisocial behaviors and reinforce positive behaviors
Substance use	Increased supervision, motivation enhancement techniques to reduce use

Psychosis

Risk Assessment

The onset of psychotic illness in a child or adolescent is a true psychiatric emergency, but ED clinicians should be mindful that chronic psychotic disorders such as schizophrenia are rare in children, so a broad differential and careful assessment is important. Young children and those with IDs can describe ego-dystonic or shameful thoughts or urges as "voices," or may have difficulty distinguishing intense fears, anxiety-driven illusions, trauma flashbacks, or even imaginary friends from visual hallucinations. Children and adolescents with mood disorders may also experience nonpsychotic hallucinations that are congruent with their mood as well as grandiose, nihilistic, or shameful delusions. OCD can present with thinking that appears psychotic, particularly in youth whose obsessions and compulsions are all internal (with compulsive thoughts rather than behaviors). Other youth who are sent to the ED for "bizarre behavior" or "responding to internal stimuli" have autism or ID; this may be undiagnosed, or the child with known autism may have a change in behavior that is perceived as psychotic but is actually related to a physical ailment or

other stressor the child cannot articulate. Information about the child's functioning at home and school, history of symptoms and treatment, recent and prior stressors or traumas is important to obtain from collateral contacts to elucidate the clinical picture.

If the child is truly psychotic, organic causes must be ruled out either before psychiatric treatment begins or concurrently to psychiatric stabilization. The medical workup should include a complete physical examination, serum tests including complete blood count, electrolytes, and liver, kidney, and thyroid tests. Toxicology screening should be completed if there is any chance of substance use or accidental ingestion, and other tests such as lyme, erythrocyte sedimentation rate, rapid plasma regain, brain imaging, lumbar puncture for cerebrospinal fluid analysis (for cases of suspected encephalitis) should be obtained, in collaboration with pediatric and neurology consultation, depending on the patient's history and current symptoms.

Management

Youth with psychosis, related to schizophrenia, bipolar disorder, depression, or OCD, can rarely be stabilized in a few hours in the ED and generally require inpatient hospitalization for stabilization. Whenever possible, treatment should begin as quickly as possible (in the ED if necessary) as psychotic patients can act erratically and because untreated psychosis is terrifying to patients and their families (58). If the psychosis is secondary to drug intoxication or accidental ingestion, the psychosis may clear in hours or days, though youth who have abused newer designer drugs such as synthetic cannabinoids and substituted cathinones may have persistent psychotic symptoms and require hospitalization for stabilization.

If the "voices" or other reported psychotic symptoms are due to anxiety, trauma, or grief, or a manifestation of ID or immaturity, the patient may be safe to return home with community treatment for their underlying disorder. The ED clinician should reassure the child and family while at the same time emphasizing the importance of follow-up psychiatric care.

Youth with Autism and Intellectual Disability

Risk Assessment

Youth with autism spectrum disorder (ASD) are nine times more likely than their neurotypical peers to go to the ED in psychiatric crisis (59). Youth with ASD and/or ID are difficult for ED clinicians as they are often medically and psychiatrically complicated, and because ED staff often lack training in working with such patients. Children and adolescents with ASD or ID are often brought to the ED for behavioral symptoms such as aggression, self-injury, inappropriate sexual behaviors, sleep cycle reversal, or running away. In the ED these children may be aggressive or

agitated due to hyperstimulation from the noise and light of the ED and the stress of an unfamiliar and unpredictable environment.

The clinician should look for changes in the environment (school vacation, changes in caregivers or environment) or physical/medical problems (constipation, dental problems, seasonal allergies, ear infections, akathisia from antipsychotic medication, fatigue due to polypharmacy, onset of puberty, or subtle seizure activity) that may be triggering behavioral symptoms. Self-stimulating, aggressive or self-injurious behaviors can be a response to frustration, anxiety, or discomfort that the child cannot communicate verbally. Considering the child's cognitive and developmental age is also crucial when evaluating problematic behaviors. For example, an adolescent boy with severe autism and moderate ID who touches a peer's breasts without permission may have little understanding of why this behavior is intrusive and offensive; hypersexuality related to mania is much less likely the cause. If environmental, medical and developmental causes can be ruled out, the clinician should consider new onset of psychiatric disorder such as mood or anxiety disorder.

Management

Awareness of techniques to work with youth with ASD and ID and small modifications to the ED milieu can help make the ED a safe and therapeutic space for patients with ASD/ID. If available, child life specialists, OT and other allied health professionals can be extremely helpful in engaging and soothing youth with ASD/ID. If such staff are not available, replicating where possible what works for the child at home or at school (such as preferred caregivers, toys or activities; soothing techniques and preferred sensory tools; and communication tools such as "baby sign language" or picture communication tools) can be very helpful. Youth with ASD/ID are often sensitive to physical intrusions, so blood draws, injections, vital signs monitoring, and other procedures should be consolidated when possible and eliminated if not necessary to the medical workup.

Medication should be used cautiously for sedation in ASD and ID patients in the ED, as they often have paradoxical reactions to medications such as benzodiazepines and diphenhydramine and often have little positive response to injectable antipsychotics. Behavioral interventions and relief of the etiology of their stress (such as effective pain control, dental care, resolution of constipation or adverse effects from polypharmacy) can lead to rapid relief and stabilization. Once the underlying problem is resolved, patients who had been extremely difficult to manage can become calm and cooperative enough to be safely discharged, particularly if the ED clinician can assist family in identifying community respite and home-based services for additional support.

Child Abuse or Maltreatment

Child Abuse or Maltreatment

Risk Assessment

Often when children present to the ED for psychiatric evaluation, the crisis lies not in the child alone, but in the psychosocial context. Cases of child abuse or maltreatment are unfortunately common and are very challenging for the ED clinician to identify and manage. Poverty, single parent households, large family size, social isolation, parental substance use, personal history of abuse in the parent, and psychiatric and developmental disorders in the child all increase risk for child abuse. Maltreatment also increases a child's vulnerability to psychiatric illness. Children rarely freely admit to abuse, parental substance abuse, domestic violence, or other crises in the family. The ED clinician must be vigilant to subtle physical signs of abuse or neglect; externalizing behaviors such as aggression, hoarding or stealing food, running away, regression in toileting, and school refusal; internalizing symptoms such as PTSD, depression, inattention, or withdrawal; and discrepancies in the child's or adults' reports that suggest that the family is actively concealing a family secret.

Management

Safety is the first priority in cases of maltreatment; if the child is being abused, if the parent is severely mentally ill and unable to care for the child, or if there is extreme violence in the home, then child protective services should be notified. The ED clinician should simultaneously work with the child, family, and any available services and supports to identify strengths in the family system that can help to stabilize the crisis. Often allowing both the child and parent to articulate the crisis and access individual and family treatment will reduce both the child's distress and the strain on the family, and increase everyone's openness to treatment.

CONSENT, CONFIDENTIALITY, AND LEGAL CONSIDERATIONS

The ED clinician should be knowledgeable about the federal, state, and institutional regulations that govern emergency psychiatric treatment and hospitalization, particularly those that dictate the emergency evaluation and treatment of minors. As mentioned for consent above, each state has specific statues governing psychiatric hospitalization for minors, generally allowing for parents or guardians to admit minor children on a voluntary basis, and also allowing for involuntary, emergency, or diagnostic admissions (51). Some states allow adolescents above a certain age, or if emancipated, to consent to their own hospitalization. Clinicians should familiarize themselves with their state statues for hospitalization of minors, as well as their institutional policies for hospitalization and consent for treatment (especially consent

for psychiatric medication).

ED clinicians must also be mindful of state and local regulations and statues regarding mandated reporting for child abuse or maltreatment, institutional abuse reporting (such as schools or residential programs), duty to third parties (also known as “Tarasoff” duties), and confidentiality of mental health, substance use and sexual health information for minors. Many states allow adolescents some degree of confidentiality vis-à-vis their parents, though if the child is in imminent danger or a danger to others, the parent should be notified. Often the child wishes to keep treatment secret from their parent or guardian due to fear of the parent’s reaction, and with the clinician’s support, may be able to safely disclose and include the parent in treatment.

Clinicians working in emergency settings often fear litigation and malpractice in settings of adverse outcomes. While there may be pressure to practice defensive medicine, the best defense is to practice excellent medicine that is well documented and supported by clinical science and best practices. Being transparent, compassionate and collaborative with patients and families can also reduce the risk of litigation.

CHAPTER 6.3.2 ■ MILIEU-BASED TREATMENT: INPATIENT AND PARTIAL HOSPITALIZATION, RESIDENTIAL TREATMENT

JOSEPH C. BLADER AND CARMEL A. FOLEY

INTRODUCTION

Because they subordinate nearly all aspects of a person's life to external control, inpatient and residential psychiatric treatments are among the most intrusive in health care. Autonomy and privacy may not be abundant in childhood, but their loss in these treatment settings is still nearly total. Separation from home under difficult circumstances and the substitution of strangers as caregivers and peers are confusing and frightening experiences for both patients and families. While admission is typically a last resort and provides some relief, parents look to clinicians for help with their own misgivings and emotional turmoil.

At the same time, the uniqueness and potency of out-of-home treatment may profoundly affect the course of illness and functioning for many youth. The leadership roles that child and adolescent psychiatrists assume in these settings therefore entail not just great responsibility for the children now in their physical custody but great opportunity as well. This chapter's goal is to orient readers: (a) to the mission of milieu-based services in today's system of care; (b) to the development and implementation of the multifaceted programming these services provide; and (c) to contextual issues bearing on leadership, administration, and quality assurance in these complex settings.

EVOLUTION OF MILIEU-BASED TREATMENTS

Confinement of the Mentally Ill

Centers that provided compassionate and humane care for the mentally ill flourished intermittently in Europe and the Arab world since classical times. Healing temples offered care and serenity, at least for the elite of these societies. In some places priests, perhaps exploiting a person's delusions, impersonated gods to provide patients with reassurance or to command changes in behavior (1). Ancient Greek physicians were probably the first to offer physiologic explanations for behavioral disturbances to replace supernatural ones. They devised various somatic therapies to rebalance or promote proper circulation of bodily fluids or "humors." While these treatments were available to the more privileged groups who could afford them, the ancients did have a protoscientific concept of mental disorder.

Nevertheless, for most of Western history, the treatment of people with psychiatric illness rates among the more ignominious of human activities. One influential Roman, Aulus Cornelius Celsus (25 BCE to 50 AD), advocated a calm environment and encouragement for the melancholic in addition to specific herbal remedies (2). However, for agitated behavior he called for punitive measures:

> "If however, it is the mind that deceives the madman, he is best treated by certain tortures. When he says or does anything wrong, he is to be coerced by starvation, fetters and flogging… To be thoroughly frightened is beneficial in this illness." (p. 303)

This strain of thought sanctioned a range of odious practices toward people with severely disordered behavior for centuries to come. In medieval times, demonic explanations for aberrant behavior and thought resurged and motivated the confinement, persecution, shackles, and harsh and neglectful treatment that dominated until the late 18th century.

The contemporary model of the psychiatric hospital originates with reforms during the 1790s in Britain (William Tuke, founding the York Retreat, which in turn influenced Benjamin Rush in America), France (Philippe Pinel at Bicêtre and Salpêtrière asylums), and Italy (Vicenzo Chiarugi at Florence's Hospital of Bonifazio). All three men's writings contributed to the modern nosologic approach to mental illness based on lucid descriptions of symptoms and observed course. In the United States and Britain, facilities for the care of those with chronically debilitating mental illness became a function of local government.

This wave of reform and the infusion of public investment, along with an optimistic view that more humane treatment would also cure patients, helped stimulate a significant growth of institutions for the mentally ill beginning in the early 1800s. Many facilities were set in locations removed from the main population centers from which their residents came. It was almost inevitable, though, that the burdens of increasing urbanization and migration, economic dislocation, and the infectious epidemics of subsequent eras, along with the fact that more humane care was not necessarily curative, combined to strain these resources. Underfunding, public discouragement, and a growing patient population degraded many publicly supported facilities into quite dismal places well into the 20th century. However, the deinstitutionalization movement enabled by the Community Mental Health Act (CMHA) of 1963, the development of more effective treatments, and a generally prosperous economy, led to a major reduction in the census of large long-term hospitals. Inpatient psychiatric treatment gradually came to be seen as another health service, rather than a custodial one, and acute units developed in general hospitals where relatively short stays for episodic crises became the norm. Nevertheless, the ambitious aims of the CMHA were never fully funded and it is unlikely that adequate

outpatient supports exist to offset the historically low availability of inpatient beds for those with severe mental illness.

The larger historical context of psychiatric hospitalization, and enduring apprehensions about the people who need it, continue to imbue inpatient psychiatry with arguably the most negative stigma among medical treatments today.

Children's Inpatient Treatment

Both before and after the reforms of the early 1800s, we know that disturbed children and adolescents were at times placed in these facilities along with adults. Beyond a few scholarly reports that documented the occurrence of severe mental illness in the young as scientific curiosity, little is known about the care and outcomes of children in asylums. The first dedicated child psychiatric inpatient units as such in the United States were created in 1920s and 1930s, mostly as custodial services for children with postencephalitic brain disorders. The prevailing philosophies of these settings and their successors are discussed below.

By the mid-1970s, inpatient services for children and adolescents proliferated, chiefly in private sector general and specialty psychiatric hospitals. The U.S. Supreme Court's 1985 decision in *Massachusetts vs. Metropolitan* (3) supported mental health coverage by insurance plans, and earlier the *Parham vs. J.R.* decision affirmed that parents' could compel admission to psychiatric inpatient care for an unwilling minor, much as any other necessary medical treatment (4). Lengths of stay were rather extensive, standards for admission were liberal, and many inpatient settings adopted rather high, if subjective, criteria for judging wellness to warrant discharge. Direct-to-consumer advertising by these facilities, aimed at parents worried about their sullen or unruly teenagers, became commonplace. Inpatient care also served an evaluative purpose, with some referrals made for diagnostic clarification.

However, by the early 1990s this trend rapidly reversed. Scandals plagued certain for-profit facilities. Managed care established increasingly strict criteria in order to justify inpatient admission. The *Parham* decision was partially blamed for the ease with which parents could have their adolescents psychiatrically hospitalized, often for rebellious or obnoxious behavior alone. Lengths of stay plummeted, though actual rates of admission for young people have increased (5).

In the public sector, policy makers also recognized that a disproportionate amount of the mental healthcare dollar was spent on very costly inpatient care that could be redirected to less expensive community-based options that were more appropriate for many children.

Child advocates who had earlier called for more community-based resources to help impaired children remain at home (6,7) found that cost concerns were also aligning policy makers' interests toward less restrictive alternatives. "Continuum-of-

care” principles by federal, state, and county mental health agencies increased the array of community-based programming. Such services included in-home and out-of-home respite services, supportive case management, therapeutic after school programs, innovative programs based on “blended funding” from several agencies, etc., all aimed at avoiding or reducing hospitalizations and optimizing a child’s opportunities for successful and safe life in their communities. Localities, though, still vary widely in the availability and quality of these resources. Moreover, some evaluation projects raised the prospect that such enhanced services do not necessarily produce more favorable outcomes, although families do find them preferable to service systems that lack them (8).

At the present time, inpatient psychiatric treatment in the United States is regarded, properly, as an expensive resource to be used sparingly and as a last resort for the most ill of youngsters. Comparatively few children now depend on long-term psychiatric inpatient settings to receive care, and acute-care lengths of stay are shorter. Current concerns in children’s mental health are almost mirror images of older ones. Worries about excessive use and long stays have been replaced by concern that stays are too short to enable satisfactory transitions of children back home and the dearth of outpatient and supportive services in many areas cause facilities to discharge very fragile youngsters into a void unable to provide an appropriate level of care.

Evolution of Treatment Philosophy

The first children’s units were essentially custodial in emphasis due to the mostly organic impairments of the patient population (9). Most would be regarded today as intellectually disabled, whether by congenital or acquired (usually infectious) factors.

By the mid-20th century, psychoanalytic thinking dominated child and adolescent psychiatry. Child psychoanalytic theories emphasized the primacy of interpersonal experience in development and emotional disturbances. Early attachment, nurturance, attunement, and gradual promotion of autonomy provide the template for personality development (10). Separation of the child from his or her supposedly pathogenic home environment, now regarded as a necessary evil, was then felt “to be the first requirement for successful treatment … since he is comparatively helpless to reorder his own surroundings or change them to better suit his needs” (11). Inpatient and residential settings for disturbed children had the premise that a more capable caregiving environment offered corrective experiences that would allay basic insecurities and foster ego development. Residential settings also were thought to provide an empathic surrogate “holding environment” (12) that would help the child manage his or her destructive urges or disorganized behavior. There was no particular expectation that this would be a rapid or easy process and long stays were

common.

In the 1960s and 1970s, learning theories from experimental psychology, especially its neobehaviorist schools, acquired greater traction in clinical psychology. Environmental manipulation to modify behavior, known broadly as behavior modification or behavior therapy, gained wider application in facilities for developmentally impaired and chronically mentally ill adults. Approaches based on *operant conditioning* principles defined adaptive behaviors for which the individual had a deficit, and sought to promote them with rewards or reinforcers. Likewise, efforts to eliminate (or "extinguish") problematic behaviors involved withholding the consequence thought to reinforce it (such as attention or avoidance of a demanding situation) or by applying an aversive consequence. Offering patients explicit training and practice in specific behavioral skills, such as assertiveness, anger control, and social interaction, were also undertaken in a variety of formats. Influential reports showed dramatic improvements in the social engagement and activities of daily living among chronically ill adults, the acquisition of some language by autistic children, and reductions in self-abusive behavior by those with intellectual disability (13–16).

Settings that provided round-the-clock care seemed ideal for treatments that required consistent monitoring of behavior and systematic manipulation of the consequences. "Token economies" in which patients earned various privileges for prespecified behaviors, became widespread, and influenced the point or level systems common in today's inpatient and residential settings. The appeal of these systems may derive partly from their implementation on a unit-wide basis, in that many patients will share similar behavioral objectives and thus offer a common template for the whole service. In contrast, classical conditioning and applied behavioral analytic approaches are highly idiographic and the staffing of most psychiatric settings seldom permits such intense staff training and individualized implementation efforts on a routine basis. The obvious availability of a peer group also enables on-the-spot opportunities to develop and practice social and other skills. Behavioral interventions are devised to yield dividends in weeks, or at least that is the period for evaluating the usefulness of a particular treatment plan.

However, the intensity of specialized out-of-home settings that facilitates ecologic interventions of these types also reduces the likelihood that behavior changes will generalize to other settings. It is therefore desirable to involve families as much as possible to enable continuity of factors that promote behavioral stability in the hospital. Family-focused treatment did not assume a major role in the treatment of psychiatrically hospitalized children until the 1980s. In 1980, the most common type of treatment received across all settings was individual therapy, received by 89%, while family therapy was provided to only 38% (17). At that time, some settings had programs where entire families were admitted and under constant observation. Inpatient treatment had in many places evolved to involve parents and other

caregivers more actively, and had included time spent off the unit at home to practice and troubleshoot alternate ways of interaction intended to foster more adaptive behavior. More recently, as short lengths of stay became the norm and payers declined reimbursement if the child spent outside of the hospital, these practices have waned.

Pharmacotherapy now plays a prominent role in the psychiatric treatment of youth. The 1980 NIMH report indicated that 42% of child and adolescent inpatients were treated with standing psychotropic medication. It is now the rare youngster whose inpatient or residential treatment does not include medication (18–20). Initiation of medication trials is more readily approved by insurance reviewers as a justification for continuing hospital care than other interventions. The combined effect is that the role of the child psychiatrist in these settings has increasingly focused, perhaps to the detriment of other areas, on which preadmission agents were doing any good, which were potentially making things worse, and what to try next, all in the context of constrained lengths of stay with a possibly more treatment-refractory patient group.

In hospital settings, daily rounds now typically begin with the question, "Why does this child need to be in the hospital"? All hospitalizations covered by managed care plans are constantly monitored by the insurance companies' reviewers. Publicly funded care is also subject to retroactive denial of payments if inspection of the medical record is judged to lack sufficient justification for inpatient care. Although minimizing the time a child spends in a hospital is not a controversial goal, a widespread sentiment is that aggressive cost containment may have compromised care. For instance, payers often regard as inertia the observation of a child after withdrawing preadmission medications, which biases the system toward initiating new, possibly superfluous pharmacotherapy. This is another area deserving more systematic study.

OVERVIEW OF TYPES OF MILIEU SETTINGS AND THEIR PURPOSE IN A SYSTEM OF CARE

Inpatient Care

Inpatient care is now only deemed appropriate when less restrictive alternatives have been considered, have failed, or are not available. The most common reason for admission is behavior that places the child or others in danger. This may translate to suicidal ideation, intent, or attempt, or may reflect sufficient threat of aggression or actual aggression such that the caretaking system, school or home, is concerned and unable to handle the youth. It is difficult nowadays to get authorization from payers to admit for a purely diagnostic assessment. Indeed, many components of such evaluations, say, can generally be secured on an outpatient basis, and payers seldom find the value of inpatient observation a cogent rationale for admission.

The majority of short-stay psychiatric treatment is provided in units located in freestanding psychiatric hospitals or in psychiatric units in general medical/surgical hospitals. These settings generally serve children of ages 5 to 18 years. Very few programs serve a preschool population in an inpatient setting. It is common to have separate inpatient settings for children up to age 12 or 13 and for adolescents up to age 18. Some inpatient units treat children and adolescents together, or those over the age of 16 may be admitted to adult settings, but these practices derive more from necessity than philosophy. Youth inpatient settings not embedded within a medical facility often cannot admit, or decline to admit those with substantial medical needs or who are likely to require specialist consultations as part of their assessments. This can be disadvantageous in many areas of the country where only few providers of inpatient psychiatric care are not a part of a larger medical service.

Municipal and county facilities often have a public mandate to serve the local court system. Judges have the authority to mandate assessments in such units frequently for defined time frames (21 days is common). A complete assessment of the child's mental condition, including psychological testing, and a psychosocial assessment of the child's family, school, and community culminate in an advisory report to the court. This population is considered to be massively underserved with respect to psychiatric illness, the prevalence of which is now known to be quite high. To the extent that mental health services variously exist within the juvenile justice systems residential programs, they constitute another version of a psychiatric inpatient provider system for incarcerated youth.

Inpatient units can be subspecialized for the care of unique psychiatrically impaired populations. Eating disorder services are one example, which enable the more intensive medical management these youth require initially with the specialized psychiatric care that does most of the heavy lifting toward recovery adequate for the resumption of outpatient treatment. Special psychiatric units for the deaf, the blind, and for youth with co-occurring developmental disabilities, also exist. A few units exist for the treatment of chronic pain, in which psychiatric and psychological care have a prominent role. There are also numerous residential centers for adolescent substance abuse, but the involvement of psychiatrists is highly variable.

Partial Hospitalization and Day Treatment

Of the varieties of noninpatient programs, partial hospitalization is the most intensive. The clinical challenge for this level of care is the provision of short-term, crisis stabilization as an alternative to inpatient care or as a step down from inpatient care.

Partial hospital programming may be provided on an inpatient unit. Some refer to this as "unit-based aftercare." It allows the patient to continue working with the same treatment team and the same peer group rather than forcing a change for a short

period of time. Partial day hospital licenses require treatment to be no longer than 6 weeks and the provision of daily medical record documentation of progress much like an inpatient setting. However, most inpatient units have a high inpatient census and staffing is not necessarily easily expanded to cope with "day patients," so the model has obvious practical limitations.

More typically, partial hospital programs have their own staff, space, and school. Managed care review generally constrains the actual duration of the patient's involvement to only days or a couple of weeks. Since the setting is generally open, and regulation does not allow restraint or seclusion, but does permit therapeutic hold and use of a quiet room (no locked door), there are practical limitations on the degree of psychopathology for which these settings are suitable. Programmatically, the range of therapeutic services are similar to inpatient settings, and include, individual, group, and family therapies, recreation and rehabilitation therapies, medical care, and psychopharmacology.

Day treatment, sometimes referred to as "continuing day treatment," differs from partial hospitals in several ways. Length of stay is much longer, often driven by the school year's calendar. In some locations, children attending day treatment that is in a clinical facility rather than one run by the educational authority, require approval of that level of care by the home school district, since depending on state law, these authorities assume the cost of the program's educational component. Some localities oblige the home district to provide transportation to these clinical settings within a certain radius, while in others families have to make their own arrangements.

Day treatment settings usually resemble schools more than hospitals, with the addition of outpatient psychiatric care and nursing staff to help manage the setting are provided. When a psychiatric facility houses a day treatment program, it may be chartered to operate its own school. More often, the facility is partnered with a local education systems' special education division. The school service may therefore have some independence from rest of the facility. The psychiatric staff should be aware of this and maintain good rapport with all those involved in the children's care.

Since most commercial payers generally only cover acute short-term care, it is Medicaid that more commonly covers the cost of day treatment, with eligibility based upon either family's precarious finances or the child's own chronic disability. Some day treatment programs are funded entirely by units of state and local government and are therefore available regardless of means.

Partial and continuing day hospital programs occupy "open" settings, and these programs tend to be rather selective in whom they admit. Imminent danger to self or others, elopement risk, and bringing contraband to the program, all preclude successful treatment in such settings. To date, limited treatment effectiveness research suggests that partial/day treatment is a cost-effective approach for some children in crisis in lieu of hospitalization and/or as step down for inpatients (21).

Residential Treatment

Residential treatment services can resemble boarding school-like settings where the child lives, goes to school, receives therapeutic services, and all necessary medical care and psychiatric medicines in one location. The prototype for residential treatment is the "cottage" model. This model, in turn, derives from the heritage of many of these facilities as turn-of-the-century orphanages or shelters for children of destitute families, especially in the Eastern United States. The explicit goal was to emulate family living, complete with live-in "cottage parents," to the extent possible. Child guidance clinics were established at some of these facilities. The Child Welfare Act of 1915 provided widows with at least minimal support, after which the orphanage population began to decline. During the Great Depression, these same charitable entities partnered with the states and could draw down public funding to provide a wide array of services, which included care for emotionally troubled youth. Later in the 20th century, support for foster care, adoption, and small group homes eclipsed large congregate care for the parentless. The coming decades essentially completed the transformation of many of these facilities into therapeutic schools reliant on public funding.

Residential treatment facilities (RTFs) are typically licensed by state departments of mental health, and have the mission of caring for the severely psychiatrically impaired youth who do not need the constraints of an inpatient setting. By contrast, residential treatment centers (RTCs) generally come under the auspices of state departments of social service. The setting and range of services are similar, but the RTC population is generally less psychiatrically impaired and would probably be suitable for outpatient treatment were it not for adverse psychosocial circumstances that make community living inadequately supportive. Reasons may include absent or mentally ill family members or seriously damaged parent–child relationships. In some cases, an RTF may be collocated as a cottage within an RTC but with different staffing and capability for managing behavioral crises, including specialized staff training and a "quiet room."

One of the more controversial aspects of admission to RTCs has been the requirement in many states that parents relinquish custody of their children. Having parents make this wrenching decision seems intended to prevent parents fobbing off care of their children for economic reasons alone, but family advocates point to the family-blaming reasoning and discriminatory infliction of pain on the families of mentally ill children that relinquishing custody entails. Consequently, several state have abandoned this requirement.

REFERRAL AND ADMISSION

Admission Policies

Each setting has to have a realistic appraisal of its limitations since no useful purpose is served by making commitments that diminish the service's overall quality of care or safety.

Acute inpatient services tend to be the least "selective," consistent with their mission to be accessible ports of last resort in a crisis. Nevertheless, difficult situations still present themselves. For instance, many units cannot readily accommodate those with severe developmental disabilities experiencing acute behavioral disturbances, especially those lacking language, or at least needing skillful 1:1 staffing and special milieu accommodations to serve them. That level of care often means diverting available staff to the needs of one patient, rather than obtaining an addition to the staff complement for the child's stay.

Without the pressure to address acute crises, long-term inpatient, partial, day, and residential programs can be more selective, and, as less secure settings, are obliged to be. Policies vary widely as a function of facilities, resources, expertise, and availability of alternatives in the region. Facilities weigh, to varying degrees, factors like histories of substance abuse, fire setting, sexual misconduct, running away and truancy, criminal involvement, developmental needs, medical needs, prospects for family involvement, and so forth to judge appropriateness. These are not always straightforward determinations and sometimes can cause facilities, their payers, and those making referrals to collide. There has been increased vigilance by public agencies to "cherry picking" of children with less complex situations, and to the potential for some of these policies to discriminate against particular ethnic communities.

Preauthorization

This refers to the process by which the patient's insurer, accepts or rejects the referral source's clinical information. This is intended to substantiate the need for inpatient care. Sometimes, rejection by the initial reviewer leads to an immediate doctor-to-doctor review of the circumstances. Because of the time consuming nature of the authorization exercise, hospitals may employ "resource management" nurses or social workers, whose sole job is to interface with insurers or their affiliated mental health care management companies.

Parents are often unaware of their mental health benefits until a crisis develops. Only in the emergency room is it suddenly determined that the insurance plan has a unique contract for the provision of psychiatric inpatient care with one particular facility that may be geographically remote from the patient's home, to the upset of already stressed parents.

A symptom picture that puts the child or others at imminent risk of harm, failure,

or lack of available alternative services often tip the balance in favor of hospitalization. Approval for a hospital stay of one to a few days allows the admission to proceed. “Concurrent review” refers to subsequent conversations between the managed care company’s reviewer and the resource management/or physician staff about the child’s progress and readiness for discharge.

Engaging and Supporting Families

Some units, when time permits, allow parents to come and view the unit and discuss the program with staff in advance of a child’s admission. Written informational material provides useful information about visiting, phone calls, clothing, and laundry considerations, how a child’s education will be managed, how medical problems will be addressed, as well as rules about forbidden items, such as lighters, matches, cigarettes, pocket knives, drugs, etc. The same or an additional document will describe the unit’s points or levels system (usually a version of a token economy program) and how aggression to self and others may be dealt with. It is important that caregivers appreciate that the safety of all is paramount and that seclusion or restraint may be needed if someone is out of control or in imminent danger of losing control. The role of the members of the interdisciplinary team and who to contact for different concerns must be made clear.

While units may administer any medication in an emergency circumstance, it is commonplace to seek separate permission for the administration of standing medications. Justifications differ in whether this permission must be via a special consent form or an oral discussion but the discussion, including the indication for the medication, and the risks and benefits is documented in the patient record.

Every effort to join families as allies in helping the child to cope with whatever is believed to have led to hospitalization is essential to a good ongoing working relationship. The availability of chaplaincy services and interpreter services when needed can be a considerable consolation to parents. It had been customary for units to run parent management training groups, general support groups, discharge preparation groups, disorder-specific psychoeducation groups, medication education groups, as well as traditional individual family therapy meetings. Shortened lengths of stay has in many instances reduced the viability of these services, and the clinical staff who had provided them are more engaged in discharge planning and liaison.

Realistic Expectations

Given the brevity of a hospital stay, caregivers and those making referrals need to be educated that the focus of treatment on acute units is acute stabilization of the presenting problems, rather than resolution of all difficulties a child may have. Where it is suspected that a child will require a different type of school placement

upon discharge, the child will rarely be able to remain on an inpatient unit while the school district deliberates the options according to its own time guidelines. Expectations for parental involvement in treatment all need to be spelled out.

Children in Surrogate/Foster Care

A foster parent has no legal standing beyond securing emergency medical care, and therefore a representative of the foster care agency, who in turn is acting as the agent of the State Department of Social Services must be available to sign admission papers. Even after admission, consent must be obtained again for the administration of standing psychotropic medications. Many placements in foster care are voluntary, that is, a court proceeding has not terminated a parent's rights, in which case the foster care agency must make reasonable efforts to obtain the parent's consent. This can be extremely difficult for hospital units with very ill, dyscontrolled children, who without appropriate consent, cannot get on with needed treatment. If a parent refuses consent, the agency may have to go to court to override the refusal.

It sometimes becomes clear, once the child is hospitalized that the foster placement has irretrievably broken down. It is often difficult to secure a new foster home, and carry out the necessary courtship process between the child and the new foster parent on the time schedule of most inpatient units. Clarity of communication as to the limits of the stabilization role of the hospital and the agency's ongoing responsibilities to provide suitable domicile for the child should be extensively documented, prior to admission, if possible. The disordered and compromised attachments of these children are often reenacted in the inpatient setting, either with guarded, mistrustful, or unengaged behavior. Other patterns include traumatic reenactments or angry aggression meted out indiscriminately.

MULTIDISCIPLINARY ASSESSMENT

Diagnostic, Psychosocial/Developmental, Family, and Academic Assessments

Beyond the rather generic principles of good clinical practice in psychiatric assessment, we should note some special aspects of evaluation in milieu settings. Barring a true first-episode of psychosis, usually in an adolescent patient, children coming to inpatient or residential care tend to have extensive prior psychiatric histories because the conditions themselves are often chronic with early onset. Nonetheless, it is important to clarify whether the crisis at hand represents a *major departure* from a prior level of difficulties or whether it is an intensification of the same ongoing difficulties. Indeed, a behaviorally dyscontrolled youngster may be no worse symptomatically relative to the past few years, but admission is indicated just

because he or she is now much larger and so now exceeds the caregivers’ capacity to provide containment. Abrupt changes, especially if linked to a current stressor, may dispose to a better postdischarge prognosis.

Some settings use standardized rating scales as part of initial assessments. Behavioral rating scales have parent, teacher, and often, self-report versions. We strongly recommend the acquisition of teacher input, which staff can obtain via fax with appropriate parental consent, when possible. Severe dysfunction in the school setting has to be a factor in discharge planning.

Psychological testing was at one time nearly routine, but now is performed only as indicated. One tangible benefit in particular involves the elucidation of academic skills difficulties related to an unidentified learning disorder. School failure is at times wrongly attributed to poor effort or emotional disturbance, when in fact neuropsychological deficits are the main culprit.

Beyond these aspects of psychiatric assessment, each discipline will probably do their own assessment. Hospital charts and RTC records are often chock full of separate initial evaluations by nursing, social work, rehabilitation, school, speech and language, and so on.

Prior Treatment History

Previous trials of medications should be inquired about with respect to target symptoms, compounds used, optimum doses utilized, characterization of the medication trials, and patient responses. Parents are not always able to provide the necessary details, so consent to speak with previous prescribers should be sought.

Previous psychosocial treatments, including type duration, therapeutic targets, and response should similarly be ascertained. Parent past psychiatric history, substance use/abuse history, past and present treatment, and current mental functioning are highly relevant to parental capacity to care for a now ill child.

Prior placement, why it came about, duration, ability of the parent to stay involved with the child during the period of placement, the perspectives of child and parent regarding the placement, the status of reunification plans, and/or actual efforts, all provide a picture of the stability or its lack in the rearing environment. Such history also sheds light on discharge options also.

Quality of Relationships with Family and Peers

Unfortunately, psychopathology among young people is often associated with quite corrosive relationships with their caregivers. By the time of inpatient admission, some families have come to see extrusion of the child as the solution to many of their problems. While this does not bode well, it is important to understand this level of antagonism at the front end. On the other hand, children whose caregivers

acknowledge feeling quite stressed and worried by their child's problems seem less hostile, and there is some evidence that they experience better outcomes (22).

It is always appropriate to inquire about preferred activities, perceived strengths and talents, and with whom the child socializes, but these take on special significance in inpatient or residential settings. This information can serve practical purposes for treatment planning, as in the development of incentive plans, or by identifying prosocial activities in which the youth can develop improved peer relations. Among young children, how many friends they have and keep is important. Many of our patients cannot report one out-of-school relationship and parents often relate that the child's behavior hampers development of friendships and deters the parents of their peers. Adolescents, on the other hand, usually identify with some peer group, and it is important to learn whether these youth are prone to troubles of their own, are they invested in school, how much risk-taking behavior they engage in, etc. A lot of progress can be undone if a youngster gravitates back toward a problematic peer group, so alternative social venues that enable the child to gain status and recognition through some strength or talent are important aspects of discharge planning.

The ubiquity of Internet-linked devices poses special challenges to inpatient and residential settings. They are a frequent form of contraband, and quite significant for their potential to breach the privacy of other patients.

Observation in Setting

Unit staff are in a unique position to assess how children tolerate the necessary separation from family, as well as how parents and children interact at visiting time, during on-ground passes, phone contact, etc. The inpatient unit provides a readymade peer group that allows for some assessment of a given child's ability to share, form relationships, assert themselves appropriately, play, and to solve conflicts.

The unique capacity of staff across multiple domains of functioning from getting up in the morning to going to bed at night provides a rich tapestry upon which historical data and presenting symptoms are confirmed or refuted. Such observational data help detangle purely "situational pathology" from inherent dysfunction in the child him- or herself. Strengths and weaknesses observed, as well as the precise context and patterning of behavioral difficulties form the basis for individualized behavioral therapeutic plans.

However, there is evidence for a "honeymoon" type of phenomenon, where the child looks nearly asymptomatic for a time and then begins to display more difficulties (23). Shorter lengths of stay may permit staff to observe only the period of suppressed behavioral difficulty.

PROGRAMMING

Special Factors in Milieu Settings

One of the risks of congregate care for youth with psychiatric disorders is they will not bring out the best in each other, and instead may mutually reinforce self-defeating or antisocial conduct (24). Young children, for the most part, are still motivated more by adult approval and esteem than by that of their peers. By adolescence, though, this preference largely inverts, even in nonclinical groups, and those who challenge the adult-established order and provide their peers with vicarious pleasure may enjoy high status. Psychiatrically involved youngsters can rightly claim more than their fair share of misfortune, and it is well known that misery loves miserable company. However, little good comes when resentment leads to rejection of available treatment and help. An important goal for any milieu setting is to create and sustain a culture that recognizes and values progress toward therapeutic goals while dimming the allure of defeatism that often masquerades as rebellious grandstanding.

Another key milieu feature that requires vigilance concerns the treatment of more vulnerable patients, especially those with cognitive disabilities, odd behavior, or other stigmata who are incapable of sticking up for themselves. Peer harassment of these individuals is of course bullying and cannot be tolerated.

Multidisciplinary Therapeutic Components

Specific disciplines often are associated with specific treatments. It is important to be respectful and collegial with the team members who provide them. For instance, taking a patient out of another therapeutic activity for individual therapy is not only disruptive to the child, but implicitly devalues the work of a colleague. Ideally, there should be a consistent policy about when such interruptions are appropriate. When scheduling makes such conflict unavoidable, the other staff member should be alerted ahead of time. In staff meetings, everyone has an implicit theory about why a child is or is not getting better, and it is wise to recognize such perspectives. The child psychiatrist may correlate improvement with a medication change, for instance, while another therapist may emphasize a particular development in family therapy. Good leaders try to educate without being dismissive of other perspectives, and take into account reasonable attributions beside one's own.

Maintaining Social Development in an Atypical Environment

Treatment settings that segregate youth from usual community and home-living experiences for extended periods also pose a risk of institutionalization. Most facilities' programming therefore includes community trips and other off-campus activities. In fact, many RTCs provide greater opportunities for athletic and cultural

enrichment (pools, gymnasia, art studios, music lessons) with skillful supervision than would otherwise be available to many youth in their homes. A careful balance has to be struck between appropriate supervision and allowing a youngster to develop age typical skills, such as going to the store, traveling independently, and making choices about leisure time, purchases, etc. Often, excursions and other related activities are considered privileges that have to be earned, but a case can be made that at least some exposure should be contingent only on the current behavioral control to manage the outing successfully.

Milieu Management

Policies and Staff Training. Nearly all regulatory and accrediting authorities mandate that inpatient services have a written procedures and policies manual. In addition, it is very useful to have a written description for parents that orients them to the unit and its procedures. A separate version for patients will usually depict, as appropriate to age, the rules for the unit.

Service-Wide Behavioral Programs. Milieu-based therapeutic programs based on behavior modification principles are nearly ubiquitous, and go by various names, such as level, point, token economy, or behavioral systems, and we mentioned some of their underlying principles earlier. These types of programs can serve at least three purposes. First, as a means of direct therapy they can be an efficient means of promoting target behaviors that are applicable to a large number of patients and can readily incorporate some individualized behavioral goals as well.

Second, they can help provide the unit with structure, through establishment of a basis for rules to aid in the management of the service. Therefore, not only may such programs benefit a child's own difficult behavior, they also offer a form of "governance" that includes consistency and fairness. Many patients, especially younger ones, need to better restrain retaliatory impulses following provocations by peers. This goal is easier when the child can count on other ways to address their grievances, including consequences for the other child's misbehavior.

Third, these procedures have the potential to provide quantitative information on the nature and extent of patients' problems, their progress while in the hospital, and their response (or lack of) to different treatments. These data can supplement other types of clinical information and at times they serve to correct overly broad and exaggerated reports based on global narratives, such as when one recent difficult day obscures the improvements evident on those that preceded it.

As with any good behavioral therapy program, the consistency of feedback is paramount, especially praise and recognition which should be abundant but sincere. This would in many cases, accompany assignment of points or tokens for achieving the positive behavioral goals of the activity or time of day, which is well-defined. In addition, each patient has up to three or so individualized goals for which he or she

obtains praise, encouragement, corrections, as well as points earned. The actual privileges or rewards toward which points accrue can involve some that are earned daily (i.e., video game time) and some that accumulate over several days (i.e., privilege level). The former enable the patient to start each day with a "new start" and to benefit accordingly.

Overall "generic" programs of this sort may require further individualization or tailoring for the developmental or cognitive needs of patients. Modifications might include reducing exposure to triggers of upset or behavioral dyscontrol, having expectations more commensurate with current capabilities, prompts and consequences that are more tangible/visual/frequent and that are individually meaningful. Ideally, each milieu-based behavioral plan would, of course, be individualized and informed by thorough functional assessment of the problem behaviors that takes account of antecedents, consequences, and the context of these difficulties. On the other hand, it is extremely difficult to maintain consistency with a large number of staff attempting to implement even one plan, and many permutations may vitiate the whole endeavor further. With short lengths of stay, the effort is perhaps better directed toward helping families to develop behavioral support strategies most appropriate for their particular situations and working to promote generalization from hospital to community. Nonetheless, the overall point is that the rigidity of an exclusive "one-size-fits-all" approach and the infeasibility and possible inconsistencies in highly idiographic programming can each have detrimental extremes.

Safety

Because the potential for harm to oneself or others as a result of one's psychiatric illness is the chief reason for admission, the safety of patients and staff are paramount concerns. Training in early detection and proactively calming people who show developing agitation, de-escalation techniques, and the safe handling of patients when physical contact is needed are often required for those working in these settings. Measures that restrict an individual's movement to curb potential violence, such as restraints of seclusions, have to follow protocols that adhere to legal standards for their implementation. Statutes and agency directives specify the situations warranting these measures, who can order them, their duration, continuous monitoring, and so forth. The standards for youth typically differ by shorter durations for each order. These events are stressful, even traumatic, for both patients and staff. A substantial literature discusses various approaches to minimizing restraints and seclusions, and quality improvement projects focused on this goal are commonplace in psychiatric units (25,26). These often involve constant retraining of staff in de-escalation techniques, monitoring noneffective decisions, making about use of PRN medications versus changes in standing pharmacologic agents (27–29).

ORGANIZATION

The role of the psychiatrist varies considerably from one setting to the next. A child psychiatrist is often the nominal director of a hospital inpatient unit, although his or her authority and responsibility for nonphysicians depends on local practice. There are often parallel supervision structures within nursing, social work, etc. Regardless of discipline, the individual in charge of the unit must take the lead in galvanizing team members to work in a cohesive and coordinated way. In hospital settings, the psychiatrist's level of involvement in the program also varies widely. In some places, he or she participates in many therapeutic activities with patients, while in others effort is narrowly aimed at physician-specific responsibilities such as medication management and has less involvement in the milieu. Each setting responds to its unique demands and resources, and there is no basis for claiming superiority of one arrangement over another. However, when the psychiatrist's role and visibility on the unit is more limited, residents and other trainees tend to gravitate toward activities they perceive as the things the "doctors do." They should, however, be directed to attend and observe the full range of patient activities, therapies, and experiences. Otherwise, they miss the valuable opportunities for professional growth and patient understanding these settings afford.

CONCLUSIONS

The structure and the form of milieu-based treatments in child and adolescent psychiatry have shown remarkable changes in recent decades. Decreasing reliance on the institutional forms of care that prevailed in earlier erase is certain a welcome development. Nevertheless, demand and utilization for inpatient settings to manage crises have remained stable or grown for all patient groups but the elderly. The current challenge with shorter lengths of stay and thus more rapid discharge planning is aligning inpatient and residential settings with outpatient and other supportive services that can provide ongoing care for youth with this level of psychiatric severity. Postdischarge services are seldom under the control of hospital-based clinicians, but readmissions that result from the shortage of these resources are nevertheless dispiriting to families, staff, and patients themselves. The coming years will show whether we have the rigor and vision to innovate and enhance still further the quality of the children's inpatient, residential, and other hospital-based day treatments that constitute such a formidable responsibility for our discipline.

CHAPTER 6.3.3 ■ INTENSIVE IN-HOME PSYCHIATRIC TREATMENT APPROACHES

KATHLEEN M.B. BALESTRACCI, JEAN A. ADNOPOZ, MELISA D. ROWLAND, SAMANTHA J. MOFFETT, AND JOSEPH L. WOOLSTON

THE ORIGINS OF IN-HOME SERVICES

In 1982, Jane Knitzer reported the nationwide failure to meet the mental health needs of children with serious emotional disturbance (SED). Despite enthusiastic contemporary support for treatment in the least restrictive environment (and legal policy mandating it), Knitzer found that two-thirds of SED children and adolescents were either underserved or unnecessarily institutionalized (1). In addition to these primary findings regarding the dearth of non-institutional treatment options, Knitzer added that "it is not enough to develop a range of nonresidential … services for children. These services must be organized so that individual children can move easily from one to another," in short, that the mental health service sector should operate as coordinated "systems of care" (SOC) (1).

In 1984, to encourage states to address the gap between mental health needs of children and the availability of appropriate services, Congress appropriated funds for the National Institute of Mental Health's (NIMH's) Child and Adolescent Service System Program (CASSP). The aim of CASSP was to espouse core principles for the treatment of children with SED and guide states to develop programs which were adherent to them (2). CASSP forwarded the philosophy that programs should be strength based, individually tailored, developmentally appropriate, family-focused, culturally competent, community-based, and systematically coordinated (3). By 1992, every state had received CASSP planning grants to design local SOC that incorporated CASSP principles and offered a broad selection of interconnected services (4). The movement stimulated the development of community-based services, many of them in the home, and placed emphasis on the centrality of the family in decision making and treatment planning processes (5,6).

INTENSIVE IN-HOME SERVICES: AN INTRODUCTION

Intensive in-home services, also known as intensive home-based or family-based services, have been developed largely independent of one another (7). They vary regionally, with differing durations, provider qualifications, intensity, and the presence or absence of a theoretical basis. The majority of these programs share CASSP's guiding principles. These programs recognize the importance of context and ecology to a child's development, and appreciate the degree to which children

are profoundly influenced by the family system in which they live (8). They target not only the child's problematic behaviors, but also the issues present in the family system which influence the child's ability to function and may perpetuate the target behaviors (9–11). In accordance with CASSP principles, treatment plans are expected to be individualized and adapted to each child and family's assessed strengths and needs. Treatment is expected to flexible, responsive to the family's schedule, easily accessible, in the home or in the community, and may include members of the family's extended networks. Interventions aim to improve the child's functioning within all relevant systems, including school and neighborhood, and all existing providers are expected to collaborate so that services are coordinated, reasonable and understood by family members. To defer hospitalization or removal from home or community, services may also provide 24/7 crisis intervention or have access to these services. Finally, consistent with their multisystemic treatment targets, in-home services have multiply determined outcomes (12). These outcomes consist not only of reductions in out-of-home placement and symptomatology, the most common and measureable goals of intensive in-home programs, but also of improvements in measures such as child functioning, progress towards goals, family satisfaction with treatment, parent stress, academic functioning or school attendance, and involvement with the legal system (13,14).

Beyond sharing common aims and their unique treatment venue, in-home interventions share a common genesis: the original model from which they have been adapted. The child welfare system was the first to employ intensive in-home interventions as a means of preventing out-of-home placements and promoting a safe environment within the child's home. The earliest intensive, in-home model was the 4-week Homebuilders program implemented in the 1970s (15,16). Homebuilders© sparked the development of a range of home-based service models, many designed to serve targeted populations. Multisystemic therapy (MST), functional family therapy (FFT), and multi-dimensional family therapy (MDFT), all 3- to 6-month interventions, were designed to reduce antisocial behavior (substance use and criminal recidivism) among adolescents (17–19). Together, these four frequently replicated, manualized, interventions have exerted influence on the development of other in-home interventions for emotionally disturbed youth. However, while there are similarities between in-home interventions for delinquent youth and for youth with SED in duration, intensity, and multisystemic focus, there are differences in the treatment population, methods, and targets for change (20).

It is worth noting a distinction between intensive in-home treatment models and other in-home interventions such as wraparound, a care coordination intervention that may be conducted within the home (21,22). Wraparound assesses needs and connects families to concrete resources and therapeutic services, but is not, itself, therapeutic.

GROWING FIELD

In-home psychiatric interventions have been developed and funded since the mid-1980s (23,24). As of 1999, 35 states offered some form of intensive in-home service to children with SED (25). However, the provider landscape has continuously shifted with funding and legislation. For example, in 1997, the Robert Wood Johnson Foundation funded the implementation of the Mental Health Services Program for Youth (MHSPY) in eastern Massachusetts, which was supported thereafter by pooling portions of Medicaid and other state agencies' budgets (26). MHSPY was a home-based program designed to provide highly coordinated, individualized mental health and pediatric care to children with the most acute emotional and behavioral disturbances. Youth received services for an average of 17 months and showed clinically significant functional improvements. The cost of providing MHSPY was less than other available treatment services for this population (27). However, due to the level of oversight and interagency collaboration required on each case, enrollment was limited. In 2001, nine plaintiffs brought a class action lawsuit against the Commonwealth of Massachusetts (the "Rosie D." case), alleging that a "lack of intensive in-home services" contravened Medicaid's rehabilitation mandate (28). The plaintiffs cited MHSPY as a model program, but were concerned about its limited geographic range and accessibility. The judge ruled for the plaintiffs in 2006, and the court ordered an immediate expansion of in-home treatment programs (29). But without a clear strategy for implementation of the court order, no single model of home-based treatment was selected for implementation and eventually the MHSPY program lost its funding.

The in-home services field continues to grow as national policy increasingly encourages home- and community-based services (HCBS) (30). In 2003, President Bush's New Freedom Commission on Mental Health submitted a report recommending an expansion of these services to reduce the reliance on psychiatric residential treatment facilities (31). In 2005, Congress provided support for the recommendations by allocating $218 million to the development of these services in 10 states: Alaska, Florida, Georgia, Indiana, Kansas, Maryland, Mississippi, Montana, South Carolina, and Virginia. Florida was unable to secure matching state funds, however, and withdrew. Between 2007 and 2012, the remaining 9 projects enrolled more than 5,000 children at risk of out-of-home placement (32). Mississippi enrolled nearly 1,500 children, alone, in its intensive in-home intervention, Mississippi Youth Program Around the Clock (MYPAC). MYPAC enrolls SED youth up to 21 years of age, for between 3 and 9 months of services (33). Children are assigned a master's-level therapist and a wraparound care coordinator, and receive at least three visits per week between these two providers. MYPAC-enrolled youth are also connected with a psychiatrist every 4 to 6 weeks; due to the shortage of local psychiatrists, this treatment is often delivered via videoconference

(K. Plotner, personal communication, 12/8/2015). Other state in-home interventions range in duration from 3 to 6 months, with an average intensity of three visits per week. Most do not report following a specific model, but use therapists trained in various evidence-based treatments. Caseloads vary, from a low of 6 to as many as 12 cases, and programs differ in provider qualifications.

Home-based interventions have also been developed by private providers. The nonprofit organization Youth Villages delivers an in-home model (Intercept) to more than 4,500 SED youth per year across 9 states. Intercept does follow a model with a theory of change, and is unique among programs in that it collects long-term follow-up data for each participant 2 years postdischarge (34) (S. Hurley, personal communication, 1/29/2016). The for-profit Virtual Residential Program (VRP) is available in 7 states. It provides in-home step-down treatment, with an initial intensity that can range between 20 and 50 hours (35).

Home-based interventions appeal to states not only for their adherence to CASSP principles, but also for their cost effectiveness. There is considerable evidence that in-home treatment is less expensive to deliver than more restrictive services, and may realize long-term cost savings (7,27,36,37). Even so, the amount expended on home-based family therapy annually is considerable. In fiscal year 2015, Mississippi spent $17.9M delivering MYPAC to more than 840 youth (V. Donaho, personal communication, 1/7/2016) and Virginia spent $108M for in-home services delivered to an average 5,000 youth per month (B. Campbell, personal communication, 1/4/2016). In 2014, Michigan spent $59M on in-home services for 7,700 children (38). As home-based therapies continue to expand, their growth threatens to outpace their research base. Variations in delivery by state, coupled with these high expenditures, speak to the need for additional evaluation (39).

STATE OF THE EVIDENCE FOR INTENSIVE IN-HOME SERVICES

Although programs designed to treat children and youth with SED have proliferated throughout the country, the literature reports few rigorous studies of their effect. The limited number of evidence-based models may be due in part to the funding required to test existing clinical models and the challenges of monitoring fidelity and adherence in the real world. This has led to the implementation of untested interventions which have been driven by assumptions rather than data and experience. In spite of growing enthusiasm and support, some programs have been criticized for lack of structure, failure to articulate a coherent theory of change, limited knowledge of the mechanisms expected to bring about the desired change, lack of specification of active ingredients, and little or no regular evaluation for quality control (40,41). As more program developers attempt to address this challenge by implementing rigorous evaluation or randomized controlled trials that

test targeted outcomes, discover the relative value of program components and evaluate the hypothesized mechanisms through which these outcomes are achieved, we will know better which models are most likely to achieve the outcomes desired by their funders. To the extent that these interventions are multisystemic and individualized, thorough and detailed data collection on the process and content of service delivery is necessary. Likewise, efforts must be made to record and account for concurrent receipt of any other mental health services. Multiple sequential studies may be required to meet multi-tiered study aims.

One trial of an intensive in-home service for children with SED randomly assigned 279 youth to 3 different active treatment conditions, 2 of which were iterations of a 4- to 6-week home-based crisis intervention program (HBCI); the third condition was intensive care coordination (42). Six months after discharge, youth from all three conditions showed reductions in internalizing and externalizing behaviors, reductions that were not present at discharge, but there were no significant differences between the three interventions. Families receiving HBCI showed increases in family cohesion between intake and discharge, but these gains were not maintained at 6-month follow-up. The authors suggest that these changes in child and family functioning may require periodic reinforcement (42).

In an experimental study in Canada, youth were assigned to an intensive in-home intervention with a cognitive-behavioral treatment model (n = 38, after attrition) or a 5-day per week residential program utilizing solution-focused brief therapy (n = 27, after attrition) (43). Both treatments lasted 3 months and included family-focused work. On average, youth improved considerably and comparably on internalizing, externalizing, and social competence measures, both at discharge and 1-year follow-up, according to parent report. When reliable change index analyses were applied to each youth on each subscale, however, the study found that a significantly greater percentage of youth in the in-home treatment showed improved ADHD symptomatology (63% vs. 22%). Youth in the in-home arm also showed significantly greater 1-year reductions in anxiety (24% vs. 3%) and depression (26% vs. 11%). By contrast, participants in the residential program were more likely to experience increases in internalizing symptoms (43). However, the covariance of treatment environment with therapeutic modality render the findings difficult to interpret, and while the author reported random assignment of subjects, assignment was dependent on treatment slot availability and limited by cases prohibited from being waitlisted.

MST OVERVIEW

MST is one of the few models that has developed an evidence base. MST Psychiatric is recognized as an evidence-based practice by the Substance Abuse and Mental Health Services Administration (SAMHSA) National Registry of Evidence-Based Programs (NREPP) and by the National Institute of Justices searchable database,

Crime Solutions.gov. MST is an intensive home-based family therapy, originally developed in the 1980s to treat delinquent youth at risk of out-of-home placement due to incarceration. Since its inception, this model has been evaluated by 55 published outcome, implementation, and benchmarking studies. Thirty-four of the 55 studies have been conducted by independent researchers and 25 are randomized clinical trials (17). While initial MST treat model development and research focused on serious juvenile offenders and adolescents with serious conduct problems, success with these populations led to the development and evaluation of several adaptations of the model. MST adaptations have been created and empirically evaluated for: delinquents with diagnosed comorbid substance abuse and dependence; juvenile sex offenders; families at risk of disruption due to maltreatment; adolescents with chronic health care conditions; and youths presenting with SED. This section of the chapter will focus on the later adaptation, MST Psychiatric (44).

MST PSYCHIATRIC DESCRIPTION

MST Psychiatric is an adaptation of MST specifically designed to serve families with youth at imminent risk of out-of-home placement due to serious psychiatric symptoms. Often these symptoms are comorbid with behavioral and substance use problems. Specifically, the intervention targets youth ages 9 to 17 years at imminent risk of out-of-home placement in a mental health or correctional mental health treatment facility due to serious behavioral problems and co-occurring mental health symptoms such as drug use/abuse, thought disorder, bipolar affective disorder, depression, anxiety and/or suicidal behaviors. The goal of MST Psychiatric is to diminish substance use, improve behavioral problems, mental health symptoms, suicidal behaviors, and family relations while increasing the amount of time youth spend going to school and living in home-based placements.

MST PSYCHIATRIC TRAINING AND COMPONENTS

MST Psychiatric clinicians receive standard MST training and ongoing quality assurance (QA) support (17) as well as supplemental trainings designed to address: (a) safety risks associated with suicidal, homicidal, and psychotic behaviors in youth and family members; (b) integration of evidence-based psychiatric and psychopharmacologic interventions for youth and caregivers; (c) treatment of adolescent and caregiver substance use/abuse utilizing an evidence-based treatment, contingency management or CM (45); and (d) evidence-based assessment and treatment of youth and caregiver mental illness including anxiety disorders, depression, bipolar affective disorder, thought disorders, attention-deficit hyperactivity disorder, impulse control difficulties, and symptoms of borderline

personality disorder.

This adaptation of MST has been modified to incorporate a part-time child psychiatrist (20% FTE) and a full-time bachelor's level crisis caseworker. Otherwise, the team configuration mirrors routine MST with one or two teams of three to four full-time masters-level therapists, working with a full-time experienced MST supervisor serving caseloads of four families for 4 to 6 months. MST has an extensive training and QA protocol which includes intensive well-specified weekly team supervision plus weekly consultation and quarterly booster trainings with an MST expert consultant. All trainings are manualized and the QA process includes routine monitoring of therapist adherence to treatment utilizing evidence-based adherence measures based on caregiver report of therapist behavior as well as supervisor, and consultant adherence monitoring (17).

MST PSYCHIATRIC—ADAPTATION DEVELOPMENT AND RESEARCH HISTORY

As described by lead researchers in the field of mental health services research (46), the development and dissemination of evidence-based practice often follows a series of defined stages. As a rule, evidence-based treatment programs are developed and evaluated first in ideal or university-based settings (*efficacy trials*). Those that are promising move into real-world settings for evaluation (*effectiveness trials*), followed by replication in real-world settings in which the model developers are less involved (*transportability pilots*). If all goes well for the evidence-based practice in each of these stages, it emerges, often more than 20 years after the initial trial, sustainable, replicable and ready for *mature transport* into community-based settings without the need for direct developer involvement. The next section of this chapter will highlight the key outcomes for MST Psychiatric, which more than 20 years since its first evaluation, is on the border between the *transportability pilots* and *mature transport* stages.

RANDOMIZED CONTROLLED TRIAL 1, EFFICACY STUDY, MST AS AN ALTERNATIVE TO PSYCHIATRIC HOSPITALIZATION

MST Psychiatric was first developed and evaluated in a randomized clinical trial funded by the NIMH. The clinical portion of this study was conducted from 1994 to 1999 and included 156 Medicaid or crisis-funded families with youth accepted for inpatient admission into a university psychiatric hospital. Half of these youth received MST while half were admitted to the psychiatric hospital and received routine care after discharge. Findings from this trial are described in four

publications (20,47–49). In summary, there was one statistically significant finding favoring youth in the control condition. These youth demonstrated higher self-esteem based on the Family Friends and Self Measure (50) at the time they were discharged from the hospital than their counterparts in MST at approximately 2 weeks from intake (20). Analyses of data collected at 4 months or posttreatment for MST (20,47) revealed that MST caregivers and teachers reported significant improvements in youth externalizing symptoms on the Child Behavior Checklist or CBC (51) compared the control condition. MST youth and caregivers also reported significantly improved family functioning on the Family Adaptability and Cohesion Scale (52) and improved youth and caregiver satisfaction relative to usual services families. Other important significant findings posttreatment for MST included reduced hospitalization (73%) reduced days in other out-of-home placements (49%), and increased time spent in school. One of the most important findings for the trial came approximately 16 months after intake, at 1-year follow-up (48) when youth that had received MST reported a significant reduction in suicide attempts on the Youth Risk Behavior Survey (53) relative to youth in the control condition. Analyses of other data from this time period (16 months from intake) reveal (49) that: (a) across treatment conditions and respondents psychopathology symptoms improved to subclinical range by 12 to 16 months; (b) groups reached improved symptoms with significantly different trajectories (MST improved more rapidly); (c) during treatment (4 months), MST was significantly better at promoting youths functional outcomes such as time in school and living at home, yet these improvements were not maintained posttreatment. At 1-year follow-up (16 months), both groups had similar rates of school attendance and out-of-home placements. Outcomes from this trial let to the next study.

RANDOMIZED CONTROLLED TRIAL 2, EFFECTIVENESS STUDY, HAWAII CONTINUUM OF CARE PROJECT

Funded by the Hawaii Department of Health and Adolescent Mental Health Division, the Annie E. Casey Foundation and the National Institute on Drug Abuse, this randomized clinical trial was designed to determine if an MST-based continuum of mental health treatments spanning from home-based to foster care and inpatient services would be more effective than routine services provided in Hawaii's newly created continuum of care. MST Psychiatric was the model of MST utilized for this project which served families with youth ages 9 to 17 at imminent risk of out-of-home placement due to comorbid serious mental health and behavioral problems. The study was terminated early due to difficulties obtaining adequate participants and an inability to foster the development of a true continuum of services. Data from the 31 youth and families completing treatment and 6-month follow-up measures reveal the following significant findings favoring MST over youth in the control condition (54):

(a) decreased externalizing symptoms by youth report on the Achenbach Youth Self Report or YSR (55); (b) decreased internalizing symptoms by youth report on the YSR (55); (c) decreased youth self-reported minor delinquency on Elliott's Self-Reported Delinquency Scale (56); (d) decreased days (68%) in out-of-home placement; (e) increased days (42%) in regular school setting; (f) marginally significant improvements in youth criminal activity based on arrest records; and (g) marginally significant improvements in caregiver satisfaction with social supports. Experience with this effectiveness study led to the next trial of MST Psychiatric, again in a community-based setting serving youth within a continuum of care.

RANDOMIZED CONTROLLED TRIAL 3, EFFECTIVENESS STUDY, PHILADELPHIA CONTINUUM OF CARE PROJECT

Funded by the City of Philadelphia's Department of Health and Behavioral Health System and the Annie E. Casey Foundation, this randomized clinical trial was designed to evaluate the effectiveness of an MST continuum of services in treating juvenile offenders, ages 10 to 16 with a mental health diagnosis, at imminent risk of out-of-home placement due to comorbid psychiatric and/or substance use problems. All youth in the control condition were admitted to a residential treatment center and the majority of these were still in placement at 6 and 12 months postintake. Sixty-three youth reached 6-month follow-up and 44 reached 12-month follow-up before funding sources for the project ended. While results of this trial have not been published in a peer-reviewed journal, findings are outlined in a report submitted to the Annie E. Casey Foundation (57). Statistically significant findings at 6 months postrecruitment (n = 63) favoring MST in this study include: (a) decreased internalizing symptoms by youth and caregiver report on the CBC (51,55); (b) decreased caregiver self-report of alcohol use on the Personal Experience Inventory (58); (c) increased family cohesion by youth report (52); and (d) increased days in community-based placements (home- and MST-based therapeutic foster care). Meanwhile, youth in the usual services condition spent significantly more days in residential placement. In fact, since most youth in the usual services condition did not return home during the study, it was difficult to obtain accurate measures of family functioning and caregiver reports of youth functioning for these families at 6- and 12-month follow-up. However, studies of the relationship between adherence to the MST treatment protocol and clinical indicators at 6 and 12 months revealed significant findings. Specifically, caregiver report of therapist adherence on the MST Therapist Adherence Measure or TAM (17) predicted: (a) improved discipline at 6 and 12 months and (b) a trend toward improved family cohesion (52) at 12 months. Importantly, independent observer ratings of MST adherence on audiotaped sessions predicted decreased caregiver psychiatric symptoms on the Brief Symptom Inventory or BSI (59) at 12 months.

TRANSPORTABILITY PROJECT, ARROW PROGRAM (2010–PRESENT)

Funded by the Robin Hood Foundation, the Arrow Program, housed within the New York Foundling Agency, is designed to provide MST Psychiatric treatment across three boroughs (Manhattan, Queens, Brooklyn) for families served by New York City, Administration for Children's Services' (ACS) Juvenile Justice Initiative (JJI) and Family Assessment Program (FAP) when the youth or caregivers have psychiatric service needs that are too intense for routine MST or the other home-based models provided by these initiatives. JJI youth are delinquents court-ordered to out-of-home placement due to criminal behavior. The FAP program serves families that have filed with ACS to have their children removed from the home due to unruly or unmanageable behavior. This project does not have an experimental design, yet substantial data are collected at pre- and posttreatment for all families served. From the project's inception in March 2010 through December 2013, data were collected on 112 families. Highlights of these outcomes are described in an annual report provided to the Robin Hood Foundation in 2013 (60). Statistically significant findings for MST Psychiatric youth based on data collected at pre- and posttreatment (4 to 6 months) revealed: (a) reductions in total problem behaviors, externalizing and internalizing behaviors by caregiver report on the CBC (51); (b) caregiver self-reports of improved levels of psychological distress, interpersonal sensitivity, depression, paranoid ideation, psychoticism, somatization, hostility, and fewer overall symptoms on the BSI (59); (c) caregiver reports of improved family cohesion (52). In summary, the Arrow project is an example of a standalone MST Psychiatric team working effectively with children and families that represent some of the highest-end users of child welfare (ACS) and juvenile justice resources in New York City.

BLUE SKY CONTINUUM OF CARE PROJECT 2007–PRESENT

Building from prior experience in Hawaii and Philadelphia, this project takes a different approach to providing a continuum of services for delinquent youth at risk of placement. In this study, MST Psychiatric has joined forces with two other evidence-based practices, FFT and Multidimensional Treatment Foster Care (MTFC) to create an integrated treatment continuum of services. Youth slated for out-of-home placement due to criminal behavior, often with comorbid psychiatric symptoms, are referred to the Blue Sky Continuum of Care by the legal system. Within this continuum, the three models work together to provide seamless, integrated clinical services based on the needs of the youth and family. This project

has been up and running since early 2007 and has served more than 650 families to date. Of these, approximately 234 have received MST Psychiatric either alone or in conjunction with MTFC and/or FFT. A randomized clinical trial of this model has just been completed with 100 youth and their families. Data from this trial are currently being evaluated.

AN ESTABLISHED, STATEWIDE IN-HOME SERVICE: IICAPS

In a climate of rapid change and little empirical evidence, few programs have been able to establish firm statewide footholds. Among those that have been broadly accepted within a single state is the Intensive In-Home Child and Adolescent Psychiatric Services (IICAPS), which has operated in Connecticut for more than a decade. This chapter provides a closer examination of this model which was founded upon a partnership between the state's child mental health authority, the state's primary funding agency for Medicaid, and the Yale Child Study Center.

IICAPS is a comprehensive home-based treatment designed, disseminated, and monitored by faculty of the Yale Child Study Center (61). IICAPS was developed at Yale in 1997 as an intensive, psychiatric intervention for children and adolescents with serious emotional and behavioral problems at risk of requiring institutional-based care, unable to be discharged from such care without intensive services, or unable to access or benefit from standard, community-based outpatient treatment (62). The IICAPS model is structured and manualized and integrates concepts and findings from developmental psychopathology to understand the multiple determinants that contribute to the presenting problems of the child and family. Interventions are grounded in three broad sets of constructs: developmental psychopathology, psychology of motivation, action and problem-solving and SOS philosophy, all of which further case conceptualization and inform treatment planning. Although IICAPS is customarily delivered by a two-person team composed of master's and bachelor's level clinicians, in some cases two master's level clinicians may compose the team. Teams carry eight cases for an expected length of stay of 6 months, although a 1-month extension can be granted for special situations. Each team is expected to hold three sessions per week; one with the child, one with the parent(s) or caregivers, and one with the family, which both members of the team attend. Other sessions involve only one team member who is either the child or the parent-specific clinician. The services provided by the team include assessment and evaluation, individual child psychotherapy, family treatment, couples counseling, service coordination, and advocacy. Supervision and training are essential elements of the model. All individuals working in IICAPS must complete 15 hours of initial training; booster trainings occur regularly throughout the year to address model delivery concerns and/or to provide topic-specific instruction and guidance. Weekly team supervision is provided by a senior mental health clinician. In addition to acting

as Medical Director, child psychiatrists serve in multiple roles within each IICAPS program as rounds leaders, supervisors, and members of the administrative group. All teams are required to attend a weekly rounds group co-led by a child psychiatrist and an IICAPS coordinator or supervisor. Each case is presented at rounds every 3 weeks, IICAPS tools are used to structure the rounds presentation and assure compliance with all billing requirements.

Fidelity to the IICAPS model is measured by clinician adherence to the IICAPS tools. Evidence supporting the continuous and simultaneous use of the treatment and QA tools throughout all phases of treatment is required of all IICAPS programs if they are to retain their status as authorized IICAPS sites. This designation qualifies IICAPS providers to bill Medicaid for the negotiated IICAPS reimbursement rate. IICAPS intervention outcomes are monitored with the help of a web-based data collection system which is managed by IICAPS services, the training, data collection, and data analytic arm of the IICAPS program.

IICAPS STRUCTURE

IICAPS treatment is delivered in three phases: Assessment & Engagement, Work & Action, and Ending & Wrap-Up and targets four domains: child, family, school, and community. A safety plan, with contingencies for 24/7 crisis management, is set in place during the first meeting. A primary task of the clinical team from the first phase of treatment to the last is to build the therapeutic alliance which although not sufficient to guarantee treatment effectiveness is essential to the process. Treatment planning begins with the co-construction of the Main Problem, the child's behavior which is likely to lead to psychiatric hospitalization. Co-construction requires the IICAPS team to join with the family in the process of identifying and rating the frequency of the problematic behaviors that concern them. Main Problems are stated in the language of the family and must refrain from being jargonistic. This process, which includes the completion of IICAPS tools and measures is followed by the establishment of goals and action steps in the four domains, which, when completed, lead to the Work & Action treatment phase.

IICAPS uses two unique tools to structure engagement and help families to recognize the possible etiology of the problems which the child presents. The Cycle of the Main Problem is a pictorial representation of the child's Main Problem, the action(s) which trigger the behavior, the feelings which these actions evoke, those things which maintain or reinforce the behavior and the possible strengths or coping mechanisms which ameliorate it. The team administers the ICE, a 20-item adaptation and enhancement of the 10-item Adverse Childhood Experiences questionnaire (63). The ICE has added 10 additional caregiver resiliency factors to the standard 10 questions that are now in common use as a means of capturing protective factors in childhood, as well (64). In addition the team constructs a genogram with each family,

to explore relational patterns, important life events, and significant relationships and ruptures over three family generations (65).

Work & Action is the central phase of treatment during which the family and the team work together to implement the treatment plan and improve the child's functioning in all targeted domains. In addition to their regularly scheduled treatment sessions, Teams are likely to observe the child in school, attend medication appointments, and work collaboratively with other providers. IICAPS' theory of change emphasizes the importance of "quality of fit" between a child and caregivers, particularly regarding family members' perceptions of a child's functioning and severity (61,62).

Treatment concludes with Ending & Wrap-Up. Teams prepare families to disengage from treatment by strengthening the bond between youth and caretakers, reflecting on progress, and connecting youth to the next appropriate level of care. In addition to obtaining final ratings of the Main Problem and treatment goals, discharge measures are administered. These assess child severity, functioning, school attendance, service utilization, and caretaker satisfaction at discharge. It is expected that children referred for IICAPS level of care will continue to require mental health treatment following discharge. Connections to post-IICAPS services are made prior to the end of the IICAPS intervention. In many instances the IICAPS team accompanies the child and family to their intake appointments with the next provider to ensure continuity of care.
FIGURE 6.3.3.1. Paired T-test result of main problem scores from intake to discharge: IICAPS treatment completers, July 1, 2009 to June 30, 2015 (*n* = 7,240).

IICAPS EVALUATION DATA

Systematic evaluation of the IICAPS intervention as delivered in all 20 sites throughout Connecticut is conducted quarterly for QA, feedback to IICAPS providers for continuous quality improvement, and for submission to state partners at the Connecticut Department of Children and Families (DCF) and to the Court Support Services Division (CSSD), the state juvenile justice organization. Between July 1, 2009 and June 30, 2015, 11,472 IICAPS episodes of care (EOCs) were closed and evaluated. The identified children served by IICAPS during this 6-year period were 59.9% male, averaged 11.6 years of age, and were racially/ethnically diverse: 14% African-American, non-Hispanic, 42% Caucasian, non-Hispanic, 37% Hispanic, and 7% multiracial or of another race. Almost all of the children receive state health care coverage through Medicaid, as private health insurance companies typically do not pay for in-home psychiatric treatment, and limited funds are available through DCF to provide IICAPS to uninsured or privately insured children and families. They were referred to IICAPS by a range of sources, including DCF, CSSD, psychiatric hospitals, outpatient clinics, other community service providers, and schools. Of these closed cases, 7,883 (68.7%) completed IICAPS treatment. Outcomes for these completed cases are presented in Tables 6.3.3.1 through 6.3.3.3 and Figure 6.3.3.1.

TABLE 6.3.3.1

TOTAL PSYCHIATRIC HOSPITAL STAYS, HOSPITAL DAYS, AND EMERGENCY DEPARTMENT VISITS: IICAPS TREATMENT COMPLETERS, JULY 1, 2009 TO JUNE 30, 2015 (*N* = 7,883)

SUQ Event	# During 180 Days prior to IICAPS	# During IICAPS EOC (Mean Duration = 178 Days)	% Change
Psychiatric inpatient admissions	2,748	1,251	–54.5%
Psychiatric inpatient days	38,099	12,997	–65.9%
Emergency department visits	3,635	2,294	–36.9%

TABLE 6.3.3.2

McNEMAR'S TEST COMPARING CHILDREN WITH AT LEAST ONE PSYCHIATRIC HOSPITAL STAY OR EMERGENCY DEPARTMENT VISIT PRIOR TO IICAPS VERSUS DURING IICAPS: IICAPS TREATMENT COMPLETERS, JULY 1, 2009 TO JUNE 30, 2015

	During IICAPS[a]		
	At Least One Hospital Admission (*n* = 953)	No Admissions (*n* = 6,724)	McNemar's Test
Prior to IICAPS			
At least one hospital admission (*N* = 2,061)	489	1,572	X^2 = 603.0, 1, $p <$ 0.001

No admissions (N = 5,816)	464	5,352	

	During IICAPS[a]		
	At Least One ED Visit (n = 1,560)	No ED Visits (n = 6,321)	McNemar's Test
Prior to IICAPS			
At least one ED visit (N = 2,550)	826	1,724	X^2 = 398.7, 1, p < 0.001
No ED visits (N = 5,331)	734	4,597	

[a]Missing hospital data = 6; missing ED visit data = 2.

Psychiatric Hospitalization and Emergency Department Use: Table 6.3.3.1 provides data on psychiatric hospital admissions, length of hospital stay, and emergency department visits during the 180 days prior to IICAPS intake and for the duration of the IICAPS intervention (mean duration = 178 days) for children with completed EOCs. There were considerable decreases in the total number of psychiatric inpatient admissions, the total number of psychiatric inpatient days, and the total number of emergency department visits for behavioral health reasons among treatment completers during IICAPS from the 180-day period prior to IICAPS. The decrease in psychiatric inpatient admissions was 54.5%, the decrease in psychiatric inpatient days 65.9%, the decrease in emergency department visits was 36.9%. Table 6.3.3.2 provides results from McNemar's test for differences in the number of children with at least one psychiatric inpatient admission or emergency department visit in the 180 days prior to IICAPS intake and during IICAPS. These data indicate statistically significant reductions in both the number of children with a psychiatric hospitalization and the number of children with an emergency department visit during IICAPS.

Ohio Scales Outcome Data: The Ohio Youth Problem, Functioning, and Satisfaction Scales (the "Ohio Scales") (66) were developed for clinical assessment and outcome measurement, and allow for report of child problem severity and functioning from three sources: the parent/primary caretaker of children ages 5 to 18 years, the worker/clinician providing treatment to a child ages 5 to 18 years, and youth between the ages of 12 and 18 years. Additionally, questions for measuring parent and youth hopefulness and satisfaction are included in the parent report and youth report Ohio Scales forms. In IICAPS, the Ohio Scales are administered to a parent/primary caregiver and youth 12 years and older at intake and discharge; likewise, a clinician on the IICAPS Team fills out the form at these two times.

Table 6.3.3.3 provides mean intake and discharge scores and mean differences for each Ohio Scales domain per each reporter. Data indicate statistically significant changes in all domains per parent, youth, and worker report. The Problem Severity mean difference scores per parent report (–12.6) and worker report (–12.3) surpass

the Reliable Change threshold identified by the Ohio Scales developers[1] and mean discharge scores are within one point of the nonclinical range (per parent report) and at the nonclinical range (per worker report) for this domain (a score below 20). Mean differences for scores in the Functioning domain per parent report (9.4) and worker report (10.2) also surpass the Reliable Change threshold for that domain[1]; mean Functioning scores at discharge are two to three points shy of reaching the nonclinical range at discharge (above 51 points per parent and worker report, and above 60 per youth report).

TABLE 6.3.3.3

PAIRED T-TEST RESULTS OF OHIO DOMAIN SCORES AT INTAKE AND DISCHARGE: IICAPS TREATMENT COMPLETERS, JULY 1, 2009 TO JUNE 30, 2015

Domains		*N*	Mean Intake Score	Mean Discharge Score	Mean Difference (s.d.)	t-value
Parent report	Problem severity	7,278	33.5	20.9	–12.6 (15.5)	–69.4[a]
	Hopefulness[b]	7,276	12.9	10.0	–2.9 (4.5)	–54.0[a]
	Satisfaction[b]	7,253	8.4	5.5	–2.8 (4.5)	–53.6[a]
	Functioning	7,266	39.7	49.1	9.4 (14.8)	542[a]
Youth report	Problem severity	3,721	26.1	16.8	–9.3 (14.7)	–38.7[a]
	Hopefulness[b]	3,707	11.0	9.3	–1.7 (4.2)	–25.2[a]
	Satisfaction[b]	3,700	10.0	7.5	–2.5 (5.1)	–30.1[a]
	Functioning	3,715	52.6	58.4	5.8 (14.5)	24.4[a]
Worker report	Problem severity	7,490	32.1	20.0	–12.3 (13.8)	–75.2[a]
	Functioning	7,490	38.1	48.3	10.2 (13.4)	65.8 [a]

[a]p = <0.001
[b]Decreasing scores in the hopefulness and satisfaction domains indicate increasing hopefulness and satisfaction, respectively.

In the Hopefulness domain, there are statistically significant changes indicated per parent and youth report (a 2.9 point improvement in parent Hopefulness and a 1.7 point improvement in youth Hopefulness). Likewise, both parent and youth mean scores indicate improved Satisfaction with IICAPS over mental health services received by the child prior to IICAPS (a 2.8 point improvement per parent report and a 2.5 point improvement per youth report).

Main Problem Outcome: The Main Problem is rated on a 10 point scale from 1 (indicating that the child is at imminent risk of injury to self or others and is gravely

disabled) to 10 (no behavioral disturbance). Figure 6.3.3.1 provides data on changes in the Main Problem rating from the initial rating (or in absence of an initial rating, the baseline rating) to the discharge rating. Among closed cases completing treatment, the mean difference in the Main Problem rating from intake to discharge was 3.5 points ($t = 127.6$, $p < 0.001$), indicating considerable improvement in child behavior as identified in the Main Problem.

These data, indicating reduced use of psychiatric hospital care, decreasing problem severity and increasing child functioning at the completion of IICAPS provide support for this intervention among children with SED and their families. Ongoing systematic evaluation of these data, and data on model fidelity: completion of the model-specific IICAPS tools, establishment and rating of the Main Problem and of treatment goals and action steps, and adherence to model duration of care and service intensity expectations, has provided important information for monitoring delivery of the model throughout Connecticut and identifying the positive results of this intensive in-home intervention.

Additional analyses conducted with data from 7,169 youth and their families participating in IICAPS with cases closed between July 2006 and June 2012 used a "Multi-Informant, Latent Consensus" (MILC) approach to examine Ohio Scales data per youth, parent, and worker report (67). Data from the IICAPS sample were compared to a community benchmark estimated from data published by the Ohio Scales developers and colleagues (68), indicating that the Ohio Scales Functioning (MILC score) for the IICAPS youth was dramatically lower (over 3 standard deviations) than the community benchmark, and the Ohio Scales Problem Severity was dramatically higher (over 1.5 standard deviations) than the community benchmark. Mean estimates of Functioning and Problem Severity assessed at discharge from IICAPS were much closer to the community benchmarks with an average increase in Functioning of approximately one standard deviation and a decrease in Problem Severity of nearly the same size.

Confirming these evaluation findings with a control group and identifying the mechanisms by which these positive results are obtained is the aim of a randomized controlled trial of IICAPS undertaken in May 2011. Randomized to either IICAPS or a home-based care coordination model, children and families were followed for 12 months: during the delivery of the study treatment for 6 to 7 months and for a 5- to 6-month posttreatment follow-up period. Data on child behavior, mental health symptoms, and mental health service utilization, parenting practices and parental perception of the child, family problem solving, and parent mental health symptoms were collected at enrollment, following study treatment, and at the end of the posttreatment follow-up from a parent/primary caregiver. Data were requested from schools on absences, suspensions, and other disciplinary actions taken with the identified child, and as was teacher data on child behavior. Analysis of these data is underway to determine the effectiveness of IICAPS as compared to the control in

reducing psychiatric hospitalization and decreasing out of control behavior, and identify the influence of parenting practices, parental perception, and family problem solving on these outcomes.

CONCLUSION

In-home treatment does not signify a treatment modality, rather it locates the site at which some type of service which is likely to be consistent with CASSP principles is provided. Over the past three decades interventions which are delivered in the home and purport to offer mental health treatment for children and youth with SED and their families have proliferated most often without regard to their effectiveness and at a significant cost to the federal, state and local funding sources that support their implementation.

MST Psychiatric stands out as an evidence-based practice which has evolved over 20 years in a manner consistent with research on the development and implementation of evidence-based practice (46). The earliest trial was an efficacy study which allowed for the testing and development of clinical protocols and procedures under the relatively more controlled setting provided by the university hospital and university-based therapists. Successful outcomes in this setting allowed for movement of the model into real-world settings working with increasingly difficult populations served by therapists in community-based agencies. Along the way, collection and evaluation of outcomes has played a significant role in ensuring the viability of the model as changes have been made to better meet the needs of the youth and families served.

Systematic evaluation of the delivery of IICAPS across the state of Connecticut has shown consistently positive outcomes for children with SED: reductions in psychiatric hospital admissions and days, decreased problem severity, and increased functioning. Data derived from continuous attention to QA have been used to inform programmatic improvements in the service of providing effective clinical care. Analysis of the data collected during a recently completed randomized controlled trial of IICAPS will help determine the effectiveness of this model compared to a home-based care coordination model in reducing psychiatric hospitalization and decreasing out of control behavior, and identify the influence of parenting practices, parental perception, and family problem solving which may serve as mediating variables on these outcomes.

The well-documented challenges of doing randomized, controlled trials in real-world settings characterized by multigenerational, community-wide adversity has constrained the number of existing evidence-based treatment models. The paucity of proven models has resulted in the proliferation of untested programs which claim to be effective by virtue of belonging to a class of services delivered in the home. Multiple sources of evidence, as described above, give support to the effectiveness

of in-home programs in reducing the use of institutional care, improving child and family functioning and reducing symptom severity. However, beyond the programs described above, few programs utilize a manualized protocol, provide intensive training, employ QA measures, and conduct systematic evaluations using outcome and process measures to assess the degree to which they have reached their intended programmatic goals. Importantly, the mechanisms of therapeutic action by which positive changes for children and families occur have not been thoroughly investigated. Identification of the mediators and moderators of the changes which in-home psychiatric services promise to families and funding sources alike would lead to the establishment of universal, modal practice standards with required, tested components. Movement in this direction will help practitioners, program developers, public policy makers, and funders to make clinically and fiscally sound decisions regarding this class of service and lead to much needed standardization and accountability.

CHAPTER 6.3.4 ■ COMMUNITY-BASED TREATMENT AND SERVICES

ANDRES J. PUMARIEGA AND NANCY C. WINTERS

HISTORY AND CHALLENGES IN CHILDREN'S COMMUNITY MENTAL HEALTH SERVICES

The early origins of mental health services for children in the United States emphasized a community and even a systems orientation. In the 1890s, the United States, much as today, was undergoing rapid sociocultural changes due to immigration, industrialization, and urbanization. These social strains and their impact on children and families led to marked increases in juvenile crime and status offenses. Enlightened reformers saw the need for detaining young offenders separately from adults and adjudicating them in a separate court system (juvenile courts) that emphasized rehabilitation. Thus, the new juvenile courts in Chicago and Boston established clinics that comprised the first child mental health services in the nation (1).

Their success led the Commonwealth Foundation to commission a study in the 1920s (and later provided start-up funding) to develop child guidance clinics throughout the United States, staffed with interdisciplinary teams of professionals to serve children and their families. These clinics were first primarily staffed by social workers, but later attracted psychosocially oriented pediatricians, psychologists, and later psychoanalysts (as they emigrated from Europe) and psychiatrists (as the specialty grew and developed). These clinics later served as the bases of the first child psychiatry programs in the nation. They were removed from the specialty-oriented, hospital-based medical system evolving at tertiary medical centers. They provided low cost services oriented to the needs of children and families, with treatment modalities evolving to include individual psychodynamic psychotherapy, family therapy, crisis intervention, and even day treatment programs. Many have survived to this day, and they even served as the model for the community mental health centers implemented by the Kennedy administration throughout the United States in the 1960s (1). The "medicalization" of psychiatry, starting in the 1970s and 1980s, served to move child and adolescent psychiatric services toward a more hospital-based, tertiary care setting. This left the child guidance clinics, and the community mental health centers that followed them, without significant child psychiatric input, adding to the relative neglect of the development of children's services. Many of the children previously served in these clinics were served in inpatient or residential facilities, or placed in foster care or juvenile detention facilities if they lacked third-party payment.

The modern era of community-based systems of care for children was ushered by the publication of Jane Knitzer's (2) groundbreaking book, *Unclaimed Children,* which exposed the aforementioned consequences of neglecting community-based mental health services for children and their families. Her advocacy and that of others led to the development of the Child and Adolescent Service System Program (CASSP), which assisted all 50 states in the development of an infrastructure for publicly funded community-based services. The CASSP initiative was supported by the conceptual work of Stroul and Friedman (3), which coined the term "community-based system of care for seriously emotionally disturbed children and their families" and enunciated the principles behind such systems of care. Stroul and Friedman's work spurred the development of various innovative community-based treatment modalities, as well as a number of model demonstration programs in different parts of the United States using these modalities within the context of organized interagency programs. In the early 1990s, the Robert Woods Johnson Foundation established eight pilot demonstration community systems-of-care programs in different parts of the country that demonstrated the viability of the system-of-care model, demonstrating cost savings as well as less restrictive levels of care. Starting in 1994, the CASSP program was transformed into the Child and Adolescent Branch of the Center for Mental Health Services of the Substance Abuse and Mental Health Services Administration, which established the Comprehensive Community Mental Health Services for Children and Their Families Program (4). This program has funded over 180 community systems-of-care grant sites throughout the nation in widely diverse communities and American Indian communities, with over 100,000 children and families served by them, with many included in a national evaluation. The Surgeon General's Report on mental health (5) focused many of its recommendations in the area of children's mental health around the system-of-care model and its benefits for service system reform and community-based, individualized care.

INTERFACE OF CHILD MENTAL HEALTH SERVICES WITH OTHER CHILD-SERVING SYSTEMS

A number of health and human service agencies (schools, social welfare agencies, child protective agencies, juvenile justice, and public health) have experienced the increasing impact of psychosocial morbidity experienced by children and youth. These agencies typically address pieces of the service system puzzle, with little to no coordination with other agencies often serving the same youth (6).

Juvenile Justice

In spite of the similarities in their populations, the juvenile justice and mental health

systems have significant differences in their service orientations and philosophies. The juvenile justice system has faced a recent split in its orientation, between those who still promote the principles of rehabilitation advocated by its original founders, versus those who promote a more purely punitive and public safety approach. The latter viewpoint, with its push for longer sentences and even waivers into adult courts and prisons, gathered currency as the nation witnessed a major increase in juvenile crime since the 1980s (largely in poor inner city and rural areas), as well as the long list of school shootings starting at Columbine, Colorado, in 1999 to this day. This often clashes with the treatment and services orientation of the mental health system, though the latter suffers due to the lack of focus on behavioral containment and long-term follow-up. The focus in the juvenile justice system shifted toward detention/containment, either in juvenile detention facilities or residential programs with some mental health programming and services (7).

The pressures to detain and incarcerate juveniles have led to overcrowded conditions and poor services in juvenile detention and incarceration facilities that violated several federal mandates. Chief among them is the Civil Rights of Institutionalized Persons Act (CRIPA), which mandates that states provide adequate health, mental health, and human/social services to people detained on a long-term basis under state custody. Other mandates, such as the Individuals with Disabilities Education Act, also apply to such youth. There have been well over 20 class action lawsuits involving juvenile justice systems all across the nation (7,8).

A number of studies have documented high rates of serious emotional disturbance (SED) among youth in the juvenile justice system, with estimates of approximately 50% to 70% (9,10). Youth are referred to juvenile justice due to their propensity to display aggressive or disruptive behaviors, drug offenses, and/or multiple disciplinary interventions in schools. They have similar histories as described for youth in child welfare, and were often previously served by that system. However, these youth typically have underutilized mental health services over their lifetime when compared to cohorts in other systems (11,12). There is also disproportionate representation of minorities in the population of youth served by juvenile justice, especially of African Americans and Latinos. This is both due to the poverty and adversity faced by these youth, as well as the lack of culturally competent services in mental health and other agencies. The poor level of services within juvenile justice facilities also deprives them of adequate services, with racial/ ethnic bias further preventing access to services (7,13). A mandate to reduce disproportionate minority confinement, requiring that states implement efforts to reduce such disparities, existed in federal law up until the late 1990s, but it was discontinued in spite of this serious continuing trend (7).

The trend toward the juvenile justice system becoming the “mental health system of last resort” for juveniles, as well as the public support for crime prevention, has led to increasing funding for services for juvenile offenders, including mental health

services. They are leading either to the development of closer alliances between juvenile justice and mental health, or at times to the development of separate mental health services within the juvenile justice system. The latter trend may increase the access and control over these services for juvenile justice, but may result in unnecessary and costly duplication of services (7).

Areas of natural collaboration between these systems are in the prevention of entry into juvenile justice, particularly into detention/incarceration, and the treatment of youth with SED into the juvenile justice system. Multisystemic Therapy (MST), Functional Family Therapy (FFT), Multidimensional Treatment Foster Care, and Brief Strategic Family Therapy have been tested extensively with youth at risk of detention and incarceration, and have resulted in significant reductions in out-of-home placement, externalizing criminal behaviors, substance abuse, rates of arrest and incarceration, and treatment costs (14). The significant reduction of arrests and incarceration by the Center for Mental Health Services (CMHS) system-of-care demonstration sites also support the value of the system-of-care model in addressing the needs of this population of youth (4,15). The Surgeon General's report on youth violence (16) also reviews a number of effective preventive interventions for youth violence and delinquency.

Child Welfare

The original mission of the child welfare system was to provide custodial care for children and youth abandoned or abused by their families, typically through the operation or support of orphanages in years past, and foster homes and group homes in later years. There has been greater recognition in recent years that children in the child welfare system have extremely high mental health needs, with prevalence rates estimated at about 50%, but are significantly underserved by mental health services (17). Already traumatized by the abuse and neglect that led to removal from their parents' care, children placed in foster care are confronted with the additional traumas of the loss of their parents, multiple relocations, uncertainty about their future, the difficult task of establishing positive attachments to new parent figures and foster siblings, and risk of abuse in foster homes. This chronic traumatization not only places them at higher risk of posttraumatic and attachment disturbances, but also disruptive disorders. They have greater difficulties in functioning at home, school, and in their communities, placing them at high risk for additional failed placements and need for residential treatment (17).

These needs led to the proliferation of residential treatment centers focused on the custodial and at times treatment needs of children in custody, particularly adolescents. Many of these facilities provide quality therapeutic and support services, but others in many states are largely unregulated in terms of the level or quality of service provision. The legal and social structures responsible for the care

of children in state custody further complicate the situation for children in the child welfare system. The courts may make decisions supporting reunification that compromise the child's physical and/or emotional safety. Ninety percent of children in foster care are returned to their biologic parents (18), and mental health services needed to support the reunification process are often inadequate. These factors have led to a rapid increase in the number of children and youth cared for within such facilities for extended periods of time. Serious problems in the delivery of their care, such as indiscriminate polypharmacy, overuse of seclusion and restraints, and abuse at the hands of direct care staff, continue to hamper the system in spite of Knitzer's (2) original admonitions in the early 1980s (17,19).

When children are in foster care, there are unique challenges to establishing effective services coordination. The child- and family-centered system-of-care model works best when the child's parents are very invested. This may be difficult for foster parents, who are often caring for multiple high-need children and are not able to commit emotionally to a child who may live with them for a short period. Foster parents also suffer from inadequate training, support (including respite services and ongoing mental health consultation), and reimbursement for the care of children, particularly those who are seriously emotionally disturbed.

Another serious problem is the child welfare system being used by families in many states as a way to access intensive mental health services for children with inadequate insurance benefits. In recent years, the expansion of Medicaid to children above the poverty line, and particularly secondary Medicaid for children with mental illness and serious emotional disturbance, has reduced this burden on the child welfare system and served to keep affected children unified with their parents. The Early Periodic Screening Detection and Treatment mandate covers periodic health and mental health screening for covered children and medical necessity authorization of treatments and services to address abnormal findings, a benefit that prevents out of home placement and is increasingly included in managed Medicaid plans (8). Another arbitrary constraint within mental health systems that increase the risk of children being placed in foster care is the lack of needed parenting support services for individuals with mental illness, while states will fund the placement of these children in foster care. A different challenge is presented by the Welfare to Work law, which requires low-income parents to return to work to maintain some of their benefits. For some parents of at-risk children, this requirement makes it exceedingly difficult to spend the time needed to address the child's emotional or behavioral problems (17).

Children in foster care and those at risk for being placed in foster care are ideal candidates for the system-of-care model, which can prevent out-of-home placement, support the strengths of the child and family, and use natural supports in the community. Wraparound programs, intensive case management programs, and therapeutic foster care are community-based interventions that have demonstrated

effectiveness with this population of children and families (17). The American Academy of Child and Adolescent Psychiatry (AACAP) and the Child Welfare League of America (20) have developed specific screening, evaluation, and service standards to address the unique needs of children in the child welfare system. There is also a growing evidence base for psychosocial interventions for children with trauma-related disorders (21). Another positive trend is that of supporting foster care within a kinship network (extended family), allowing for relationships with family members to be sustained. More states are allowing families to retain custody of their children while they are in state-supported residential care (Oregon is one example); such changes to existing laws are usually accomplished only through significant advocacy by parent groups (also, see Chapters 5.15.1, 5.15.4, and 7.3).

Education

The educational system faces the impact of increased educational demands for average students due to the increased technologic and informational demands on our society. In addition, the increasing needs of children with learning disorders and serious emotional disturbances are placing added burdens on schools. This occurs in the context of the underfunding of school districts due to downward pressures on property taxes (as exemplified by laws like Proposition 13 in California) and other unequal means of funding education and special education services. Many school districts struggle to meet the mandates of federal laws such as the Individualized Disability Education Act (IDEA) and Section 504 (which outlines services for mentally ill/emotionally disturbed children), often underidentifying children with covered disabilities and temporizing their needs informally through the services of regular classroom teachers so as to prevent added service commitments (22).

An important area of interagency systems of care is that of school-based services. These go beyond traditional school mental health consultation services and involve the colocation of health and mental health professionals within schools to provide a wide array of direct and indirect/preventive health and mental health services. School-based mental health services serve as an ideal core service for a children's system of care, providing an excellent accessible portal of entry which is nonstigmatizing, and a naturalistic setting to observe behavior and integrate interventions into a child's environment. These services are often funded through blended Medicaid fee-for-service and managed care funding augmenting limited school funding. A number of models have been implemented in communities such as Baltimore, Maryland, New York City, rural South Carolina, the state of Hawaii, and Charlotte, North Carolina, with documented success in reducing adverse morbidity and increasing access to needed services (23,24). Innovative approaches through legislation to ensure interagency collaboration in IDEA-mandated services have been promoted in California through legislation that mandates interagency collaboration in

the development and implementation of individualized educational plans when these involve domains outside of educational services (25; also, see Chapter 7.3).

Developmental Disabilities

Children and youth with developmental disabilities have significant mental health and social service needs. The prevalence of comorbidity of developmental disorders and behavioral/emotional disturbances is estimated to be quite high. In addition to mental health services, the service needs of children and youth with developmental disorders are often wider ranging, including educational services, medical services (including general pediatric, neurologic, and genetic), child welfare and social supports (with high rates of abuse and abandonment), and even juvenile justice services. The latter need is highlighted by the high prevalence of youth with Asperger disorder found in juvenile justice populations (26). However, there is little recognition of these multiple service needs in the developmental disabilities service sector, much less adequate resources to meet them. Most state governments assign responsibility for serving children with developmental disabilities to the educational system under IDEA and ignore interagency collaborative approaches for their care. However, this system is overwhelmed in meeting its educational mission and dealing with more straightforward learning disabilities. States with developmental disabilities agencies or divisions tend to underfund them, and assign similar levels of mental health benefits as for people without such disabilities in spite of their higher risks and special service needs. The adult developmental disabilities sector is also moving rapidly to deinstitutionalize individuals currently in state training schools or facilities to community care, including the few youth in such programs. The behavioral support resources and staffing needed for successfully moving such individuals to community care are very limited, leaving them functioning at lower levels than their potential, and at risk of frequent utilization of psychiatric emergency services, hospitalization, and overmedication. This has led to many states experiencing class action lawsuits over the access and quality of care for its developmentally disabled citizens (26).

Primary Health Care

Primary care providers (including pediatricians, family physicians, some internists, and primary nurse practitioners) are the first line of mental health services for children in our nation, especially in rural and underserved areas. Studies (27) have demonstrated a high prevalence of mental health need among children and youth seen in primary care practices and settings. This role is even more critical in the Medicaid-covered population, where the EPSDT benefit includes the requirement for annual screening, referral, and treatment for mental, emotional, and developmental

disorders as well as physical illness. However, primary care providers receive little to no training in child mental health and mental illness in their preservice or residency training. They are generally not trained to use the increasing number of evidence-based tools for effective screening and identification of youngsters with such needs. Access to specialist child mental health consultants and collaborators is hampered by problems with access and reimbursement. The reimbursement mechanism for the direct delivery of entry-level mental health services by primary care practitioners is shrouded in mystery and bureaucracy, as if in an effort to reduce access to such services. The carve-out model primarily used for mental health benefits under managed Medicaid keeps "medical" and "mental health" sources of funding artificially separated (28). However, primary care has the potential to be the most important system (besides the educational system) in any effective effort to prevent the developmental morbidity of undetected and untreated mental illness in our children and youth (28).

In recent years, in response to increasing challenges in access to mental health care, a strong movement toward developing clinically and cost-effective integrative and collaborative care models has gathered momentum. It is demonstrating results in greater participation by primary care in the care of people with mental health needs. In pediatric primary care, the model has primarily been a collaborative one, with pediatricians accessing pediatric mental health consultation (especially child psychiatric consultation) from collaborative "hubs" serving practices and practitioners in defined regions. These "hubs" are staffed by child and adolescent psychiatrists (CAPs), psychologists, and social workers, and provide a gamut of consultative services, including case management referral to treatment resources (particularly for psychotherapy but also intensive services), diagnostic consultation, and psychopharmacologic consultation. The consultations are mostly telephonic (between the primary care practitioner and mental health professional), but can be live evaluations of the child and family face to face or via televideo. Some of these models also include the use of systematic behavioral health screening for all children served by the participating practices, the use of secondary screening and diagnostic tools, as well as formal training of pediatric primary care providers in psychiatric diagnostic and treatment skills within their practices.

The original model program of this kind was in the state of Massachusetts, starting with a regional model and eventually expanding to cover 97% of all children in the state. The Massachusetts model, now 10 years in operation started with state funding but now includes private third-party funding as part of its funding base. The project had provided over 35,000 encounters over its first 5 years, and served over 14,000 children and adolescents with the full range of psychiatric disorders and needs. The overwhelming majority of pediatric primary care practitioners rated the services highly in terms of access and overall satisfaction (29,30). A National Network of Child Psychiatry Access Programs has been constituted, comprising programs

representing 20 states throughout the United States, with many of these programs being statewide (as in New York State and Washington State), or in the process of becoming statewide (such as New Jersey).

COMMUNITY-BASED SYSTEMS OF CARE: AN INTEGRATIVE MODEL

The CASSP principles, now referred to as community systems-of-care principles, are based on a flexible and individualized approach to service delivery for the child and family within the context of his/her home and community as an alternative to treatment in out-of-home settings, while attending to family and systems issues that impact such care. The key principles include: access to a comprehensive array of services, treatment individualized to the child's needs, treatment in the least restrictive environment possible, full utilization of family and community resources, full participation of families as partners in services planning and delivery, interagency coordination, the use of case management for services coordination, no ejection or rejection from services due to lack of "treatability" or "cooperation" with interventions, early identification and intervention, smooth transition of youth into the adult service system, effective advocacy efforts, and nondiscriminating, culturally sensitive services (3). More recently, services quality, cost-effectiveness, and outcomes and integration of evidence-based practices have received greater emphasis within community-based systems-of-care programs. Psychiatry, which was central in the traditional model, has only recently reengaged itself as a discipline in this new model. Psychiatrists continue to face challenges in establishing their position within this model and integrating their developing clinical and scientific knowledge and skills base (3).

Another important principle inherent in this approach is that of the targeting of services to children designated as "seriously emotionally disturbed," defined as having a diagnosis under the diagnostic and statistical manual of the American Psychiatric Association (31), as well as resulting impairment in function in at least one of his/her life domains (school, home, socially with peers). This definition reflects the difficulty in accurately diagnosing many children with serious functional problems, the bias against disruptive disorders (and failure to identify comorbid serious mental illness), and the lack of clarity and validity in clinical child diagnosis. Studies also suggest that the level of care received by children is only partially accounted by their clinical diagnosis, while level of function and psychosocial stressors are stronger predictors (32).

Implementation at the Clinical Level

Family-driven care is a cornerstone of the system-of-care approach and has had a

significant influence on national policy for both child and adult mental health (33–35). The child and family drive the clinical planning process through determining the goals and desired outcomes of services, selecting the composition of the interagency service planning team, evaluating the effectiveness of services, and having a meaningful role in all decisions, including those that impact funding of services. The interagency planning team typically has representatives from all the agencies involved with the child, and the team process facilitates interagency and interdisciplinary collaboration. The complementary contributions of various team members function synergistically in identifying system and community resources to promote better outcomes.

Some children and youth enter the system of care with discrete problems that can be addressed by a specific and/or time-limited service. For children with complex problems involved in multiple child-serving agencies, assessment and treatment planning should be accomplished through interdisciplinary clinical teams. These teams bring together different clinical and support resources to address the child's needs to supporting him or her and their family in their community environment. However, funding constraints due to legally mandated categorical limits could leave some needs of a child unfulfilled. Also, many families can be well served by such interagency collaborative efforts, but often a parent or a youth surrounded by a team of professionals finds the experience intimidating and has trouble feeling that they are full participants in the planning process (36).

The wraparound process is a specific model of a child- and family-driven team planning process that has been empirically tested within systems of care. Wraparound is a definable, integrated planning process that results in a unique set of community services and natural supports that are individualized for a child and family to achieve a set of positive outcomes. The wraparound process builds on the strengths of the child and family, is community based (using a balance of formal and informal supports), is outcome driven, and provides unconditional care (37). Use of a strength-based orientation and discussion of needs rather than problems promotes more active engagement of families in service planning activities. Interventions designed to reinforce strengths of the child and family may include nontraditional therapies such as specific skills training or mentored work experiences that remediate or offset deficits. These interventions generally are not included in traditional categorical mental health funding and may require flexible funds that are not assigned to specific service types (38). For example, a youth at risk for substance abuse might receive funding for prosocial activities such as a health club membership or computer training. It has been noted that services are more likely to be effective if the wraparound process is informed by comprehensive clinical assessment addressing diagnostic and treatment issues and if the specific interventions are evidence based (39,40).

Central to this process is the development of a child and family team (CFT). Such

teams are composed primarily of nonprofessional members led by the consumer family, usually a parent. In cases of older youth as consumers, and with no parents available, the youth may serve as team leader. Empowering youth and families to assume a central role in outlining treatment goals and planning requires the involvement of specially trained individuals who can guide such families to develop such goals. Family advocates, partnering with professionals, provide the backbone of such a process. The goals for team development are to mobilize the natural support system for the family, including extended family, friends, neighbors, and natural helpers in communities. CFTs may include professionals to whom families have come to feel close, but the general rule is that teams should comprise of no more than 50% professionals. Teams should have access to professional advisors, including CAPs, who can offer advice on services, how best to access them, and on the various agencies in which the child is involved (34).

CFTs collaborate with professionals in agencies providing services. The CFT creates an overall care plan, including a crisis plan. The clinical team then negotiates their role in the crisis and care plans. This negotiation further educates families about how their child's needs could be addressed through treatment, and enables professionals to learn about the realities faced by the family. In this model, the role of the case manager is supplanted by the CFT, which is responsible for maintaining and modifying the overall care plan, with the assistance of family advocates. The most complete evolution of a system of care that supports family-centered care involves agencies blending funds and undoing categorical constraints on the use of funds, with CFTs having control over the expenditure of such funds for services they deem needed and relevant. This radically alters the relationships of service providers to consumer families, enabling poor families to have control similar to middle- or upper-class families in their child's care and encouraging programs to develop new types of resources based on the common needs of families in that community (34).

A number of studies of wraparound in different communities with diverse populations of at-risk children and families have reported positive outcomes in reduction of externalizing behavioral problems, improvement of children's level of function, reduction in out-of-home placement, improved family management skills and function, and increased consumer/family satisfaction (39,41,42). There have been recent efforts to operationalize wraparound as a *planning* model, as there has been some confusion about whether wraparound refers to the services themselves or the planning process. Recent studies on wraparound have incorporated measures such as the Wraparound Fidelity Index to ensure fidelity to the model (43).

Integration of services is fundamental to the community systems-of-care philosophy and approach. Service integration can be implemented in a variety of ways. The most fundamental is the interagency planning team, in which representatives from each agency involved with the child meet as a team to

collaborate on the child and family's behalf and develop a single, integrated service plan. Integrated treatment models allowing mental health services to be provided in schools, juvenile justice, or child welfare settings have become more prevalent. Another integration strategy is to colocate providers from different agencies in a single facility to enhance their collaboration and simplify the usually onerous task for families of accessing services from multiple agencies. Equally important in achieving service integration is the combining of funds from different agencies to form "blended" or "braided" funds to pay for services. This allows for the sharing of clinical and fiscal responsibility among agencies and decreases the likelihood of uncoordinated efforts driven by separate funding "silos" (44).

New Professional, Family, and Consumer Roles

Given the complexity of systems of care, the skills and roles that psychiatrists must display go far beyond clinical roles that are usually circumscribed and limited. Besides serving as front-line clinicians, these roles include clinical consultation and collaboration with other professionals, collaboration with family advocates and consumers, clinical team leadership, administrative leadership in a delivery organization/system, quality assurance/improvement consultation, consultation to interagency teams, and outcome evaluation/research in systems of care. CAPs, given their broad biopsychosocial and developmental perspectives, should be best able to integrate and coordinate community-based treatment delivered by multiple professionals with diverse skills. They have played critical roles in supporting some model blended funding programs, and assuring that family-driven systems of care incorporate the most recent scientific advances in child and adolescent mental health. However, given the emphasis on tertiary care models of care in the training of most CAPs, they often have not developed many of the skills needed to serve as effective members, collaborators, and leaders of these new systems (45).

There is also a need for different professional roles for other disciplines and professionals. Social workers and other masters' level professionals assume a different type of care management role in addition to their therapy roles. These new functions involve collaborating and sharing roles with family advocates, and a new approach to partnering with consumer families. Psychologists are involved in the implementation of newer evidence-based practices, such as cognitive behavioral therapy, functional behavioral analysis, and systematic measurement of behavior and strengths along with their psychodiagnostic and therapeutic roles. They may have new roles in program evaluation and quality assurance systems, working collaboratively with families in their design. Nurses are involved in a number of important roles, including greater involvement as psychiatric extenders (or, in some states, as primary psychiatric providers), and liaison roles to pediatric and health systems. Community systems of care also have important roles for educators,

formalizing their role as mental health coproviders involved in detection, triage, and behavioral interventions. Recreational and occupational therapists also have greater community involvement in schools and nonpsychiatric settings, rather than more traditional institutional settings. These roles require greater preprofessional training on development, psychopathology, and behavioral approaches (45).

The scope of family and consumer empowerment has been extended beyond the treatment setting to include their participation in a number of other roles within systems of care. These include providing case management and support services to other families, serving in quality assurance and consumer satisfaction assessment, participating in governance over system-of-care programs, and advocating for the maintenance and expansion of these programs. Organizations such as the Federation of Families for Children's Mental Health and other advocacy groups are helping to move the family and youth advocacy agenda (34).

Implementation at the Intervention Level

The President's New Freedom Commission goals and recommendations for a transformed mental health system included the dissemination of evidence-based practices as one of six major goals (46). This has provided the impetus for many states to legislate requirements around the use of evidence-based interventions. The system-of-care approach has provided a context for development of an evidence base for community-based interventions that provides alternatives to intensive treatment traditionally delivered in more restrictive settings, such as hospitals and residential treatment centers. These have been classified under the categories of community-based residential interventions (including therapeutic foster care and group homes), multimodal interventions (such as MST and FFT), service coordination and facilitation (including wraparound and intensive care management), and auxiliary and supportive services (including family education and support, mentoring, and respite services) (42). The evidence supporting these interventions will be described below, according to the schema proposed by Hoagwood et al. (47) for determining the level of evidence for mental health interventions, which includes efficacy, fidelity, and transportability, as well as Kazdin's (48) proposed levels of evidence: (1) not evaluated; (2) evaluated but unclear effects, no effects, or possible negative effects; (3) promising (some evidence); (4) well established (criteria by one system used for identifying evidence-based practice); and (5) better/best treatments (studies shown to be more effective than one or more other well-established techniques).

The treatment foster care (TFC) model was developed by Chamberlain (49) at the Oregon Social Learning Center to address problematic behaviors in children with multiple mental disorders. It includes training of foster parents, in-home therapists, and skills builders, and uses a specific model of behavior modification involving consistency, discipline, and careful monitoring of behavior and consequences (42).

Results of several studies indicate that TFC can reduce institutionalization, bring about more rapid improvement, and involves lower costs than other residential placements (49). In contrast to TFC, group homes involve creating a structured family environment for six to eight youths at a time, and the treatment model relies on the peer group milieu rather than parent–child interaction as the mediator of change. Group homes appear to be more common in the child welfare literature and have a less substantial literature than TFC (42). There have been questions about the potential for negative effects of grouping youth with similar problems together, though a robust therapeutic program can provide some efficiencies (50). MST is regarded as among the most robust evidence-based community interventions for youth with disruptive disorders (14). It combines home-based, wraparound, and cognitive-behavioral interventions that are individualized to the youth's ecologic systemic context. Its developers have paid significant attention to manualizing MST and ensuring that it is applied with adequate fidelity in their research sites. It has been evaluated in eight randomized trials, including youth at risk of detention or incarceration and youth at risk of psychiatric or substance abuse hospitalization. It has shown significant results in reducing out-of-home placement, reducing externalizing behaviors, reducing rates of recidivism, and lowered costs of treatment (14,51,52). FFT has been identified as one of the emerging evidence-based intervention programs for at-risk youth and their families. FFT can be conducted in the home or the office, and its techniques are highly specific, with its developers also having paid much attention to manualization, therapist adherence, and treatment fidelity. FFT has an established record of outcome studies that demonstrate its efficacy with a wide variety of adolescent-related problems including youth violence, drug abuse, and other delinquency-related behaviors (14,53; also, see Chapter 6.3.3).

Case management as an intervention has some overlap with wraparound, as both incorporate an assigned coordinator who participates in developing an individualized array of services and supports. Case management includes a variety of functions existing on a continuum from utilization management (or "gate-keeping"), brokering or providing access to services, coordination of services, services monitoring and evaluation, advocacy, assessment, direct family support, and direct therapeutic service provision (36). In four randomized trials and a quasiexperimental study, case management has been compared to other interventions. The more intensive case management models (closer to direct service on the continuum) generally compare favorably with other interventions in reducing out-of-home placements and other functional outcomes, but the more common "broker" model shows primarily changes in service use as opposed to better individual outcomes (42).

In the family support area, the most well-examined intervention is mentoring. Mentoring programs have become fairly widespread. Dubois et al. (54) reviewed 55

mentoring programs, finding that better results were associated with greater number of best practices, which include having more explicit structure and monitoring of expectations, screening and training of mentors, parent involvement, and youth with more limited risk factors as opposed to serious mental health problems. Respite services involve providing temporary care to provide relief to caregivers of individuals with various disabilities. With the increased emphasis in systems of care on keeping children with serious disturbances at home, families have a greater need for relief to diminish caregiver burden. There has only been one quasiexperimental study on respite, which did show decreased caregiver strain and greater optimism, fewer out-of-home placements, and improvement of children's behavioral problems in the community (55). Although the rationale for respite is responsiveness to the needs of overburdened families to support keeping children at home is not disputed, more research is needed to demonstrate its effectiveness.

The Surgeon General reports on mental health (5) and on youth violence (16) point to research evidence supporting a number of community-based interventions for children and youth, such as intensive case management, therapeutic foster care, partial hospitalization, and intensive in-home wraparound interventions. Other community-based interventions that show promise include school-based interventions, mentoring programs, family support and education programs, wilderness programs, crisis mobile outreach teams, partial hospitalization, time-limited hospitalization with coordinated community services, and family support services (39,56). Studies involving these modalities have demonstrated significantly better outcomes than traditional outpatient or residential services. These include reduced levels of externalizing and internalizing symptoms, improved family functioning, reduced utilization of more restrictive services, and improved cost-effectiveness.

One of the challenges facing community systems of care serving youth is the integration of evidence-based psychotherapeutic modalities, especially well tested, manualized interventions with demonstrated efficacy. Such interventions hold promise as broadly applicable interventions that could help address the considerable gap between mental health problems in children and the services needed to address these problems. However, there is still much work to be done in evaluating these interventions in real-world or community-based settings (39,57). Psychosocial interventions having the most empirical support include cognitive-behavioral therapy, interpersonal therapy, parent management training, parent–child interactive therapy (PCIT), and psychoeducational and cognitive-behavioral family interventions (56). Many newer systems-of-care demonstration programs are integrating such interventions into their programs, along with community-based interventions.

Pharmacotherapy in Systems of Care

Psychopharmacology has become increasingly prevalent in community settings as newer and more effective psychotropic agents have become available. These agents play an important role in the treatment of children with serious emotional and behavioral disturbance who have high rates of psychiatric comorbidity, psychosocial adversity, involvement with multiple agencies, and who are at highest risk for placement in restrictive settings (58). Advances in pharmacotherapy have engendered increased expectations that medications can help stabilize and improve the functioning of this high-risk, high-need population. It is important for systems of care to integrate effectively and fully prescribing practitioners into interdisciplinary teams and integrate pharmacologic therapies into children's wraparound plans (38). Effective use of pharmacotherapy includes systematic assessment of target symptoms, behaviors, function, and adverse effects by the whole team (including both synergistic and interfering side effects and issues such as optimal administration and dosing schedules). Ideally the team would also participate in the assessment of the efficacy of medications and interactions between pharmacotherapy and other treatment modalities and strength-based activities.

Effective pharmacotherapy requires that prescribing physicians have access to the inherent resources in a system of care, such as multiple informants to evaluate the child's symptom patterns and function in different contexts, and child and family education and support for treatment adherence. Lack of adequate contact of the children and families with the prescribing physician or medical practitioner often leads to children and families feeling uninformed, disempowered, and mistrustful of pharmacologic therapies. Pharmacotherapy in systems of care should focus on functional improvement as well as on symptomatic relief. It should also include collaboration and psychiatric consultation around medication management with other prescribing medical professionals (58). Prescribing physicians in systems of care should promote use of evidence-based systematic assessment and symptom-rating tools and become actively involved in quality improvement around pharmacologic decision-making (38,59). Attention to ethnic and cultural factors in diagnosis, metabolism of different agents, consent procedures, and attitudes toward medications are also important (60; also, see Chapters 6.1.3 and 6.1.4.1).

The national evaluation of the Comprehensive Mental Health Services Program for Children and Their Families included a substudy on the prescription of psychotropics for children in this program. One-half of the children and youth (52.6%) took at least one medication for their emotional or behavioral symptoms. The majority (85.7%) had their medications prescribed by mental health care prescribers, with the remainder (14.3%) receiving medications from primary care providers. Children and youth whose medications were prescribed by mental health care prescribers had higher levels of internalizing and externalizing symptoms at intake and at 6 months than children and youth whose medications were prescribed by primary care providers. However, the symptoms of all children and youth who

received medication improved at the same rate (4).

Implementation at the Programmatic and Service Delivery Level

Following CASSP, several early demonstration projects were initiated to develop systems of care, including those in Ventura County in California (61) and Vermont (62) and the continuum of care established by the Department of Defense CHAMPUS program at Fort Bragg, North Carolina. From 1990 to 1995, the Robert Wood Johnson Mental Health Services Program for Youth funded eight national demonstration programs. More recently, the CMHS Comprehensive Community Mental Health Services Program for Children and Their Families has funded more than 80 demonstration projects in diverse communities throughout the nation to implement systems of care. The goals of these programs have been to implement CASSP values, reduce out-of-home placements, reduce service fragmentation, and promote earlier mental health intervention to reduce functional morbidity. The latter phases of the grant program have focused on culturally diverse populations, early childhood populations, and specialized sectors such as child welfare and juvenile justice (4).

The Fort Bragg program evaluation was an early effort to perform a comparative study between a system-of-care oriented program and services as usual. It demonstrated that system coordination produced improved access to and satisfaction with services and also reduced restrictive forms of care, though costs of care were equivalent across the two models (63). However, the fact that the system-of-care group showed clinical and functional outcomes similar to those of the traditional services group contributed to a shift toward more interest in the interventions themselves (64). More positive findings have been reported in other studies. A longitudinal study of the Vermont system of care concluded that the model was cost-effective and resulted in reduced rates of out-of-home placement (65). Attkisson et al. (61) reported reduced group home and foster care expenditures in three California counties using system-of-care approaches as compared with three counties that had more traditional services. Rosenblatt (66) reviewed results of 20 community-based system-of-care studies, concluding that there were improvements in most domains assessed, including clinical status, cost, and use of restrictive placements. The multisite national evaluation of the Comprehensive Mental Health Services Program for Children and Their Families has shown improved child and family functioning, increased stability of living situation, and reduced cost of care when cost offsets in education, juvenile justice, child welfare, and general health are considered (4,15,67). It has also included a matched comparison evaluation of outcomes from system-of-care programs to treatment as usual, with significantly better functional and cost outcomes, as well as correlation of outcomes to a systems-of-care fidelity

measure (4,68,69).

However, questions remain about the effectiveness of community-based interventions and systems-of-care models in comparison to more traditional systems, which outcomes are most meaningful to measure in evaluating the model, and what the active ingredients are that produce desired outcomes. Conducting research in complex systems of care is challenging because of the difficulty of identifying comparison groups and the near impossibility of using randomized assignment since the model has been embraced nationally and to offer less would be perceived as unethical. As a result, the focus has shifted from measuring system-level outcomes to measuring clinical and functional outcomes of individual children (69).

A number of system-of-care demonstration programs that were originally grant funded have been successfully sustained. One such program with unique features is Wraparound Milwaukee in Milwaukee, Wisconsin. In existence since 1995, Wraparound Milwaukee was initially a CMHS-funded system-of-care grant. It evolved into a sustainable publicly operated care management organization that focuses on providing a range of mental health, substance abuse, social, and other supportive services to children and adolescents who are identified by child welfare or juvenile justice as being at immediate risk of placement in a residential treatment center or psychiatric hospital based on emotional, behavioral, or mental health needs (70). Wraparound Milwaukee serves approximately 600 youth during a fiscal year using a CFT process overseen by a care coordinator. Services are purchased from a blended pool from all the contracting agencies. Some of the unique features of Wraparound Milwaukee include the use of a mobile urgent treatment team that has dramatically reduced psychiatric hospital admissions, use of informal services and natural supports, and wraparound resource teams that provide specialized consultation for clinically complex youth (44). Wraparound Milwaukee receive a commendation from the President's New Freedom Commission for its effectiveness in promoting interagency services integration and individualized treatment planning with youth and family participation (46).

CHALLENGES FOR COMMUNITY-BASED SYSTEMS OF CARE

Governmental Policy Imperatives

The Surgeon General's report on mental health in 1999 (5) was a watershed event in children's mental health, as it documented emerging evidence for a variety of psychopharmacologic, psychotherapeutic, and community-based interventions. It also provided support for systems reform according to CASSP principles. This was followed by the President's New Freedom Commission on Mental Health report (46), which was charged with conducting a comprehensive study of the US mental

health service delivery system and providing recommendations to the President for improving the system. The report documented pervasive fragmentation and disorganization and called for a fundamental transformation of the nation's approach to mental health care. The report presented six major goals and recommendations for a transformed mental health system: (1) Americans understand that mental health is essential to overall health; (2) mental health is consumer and family driven; (3) disparities in mental health care are eliminated; (4) early mental health screening, assessment, and referral are common practice; (5) excellent mental health care is delivered and research is accelerated; and (6) technology is used to access mental health care and information (46). This report contains elements consistent with the system-of-care model for children with serious emotional disturbance (consumer-driven care, emphasis on resilience and recovery rather than pathology, early intervention), but applies them to all of mental health care in the United States. The President's New Freedom Commission report has provided a strong impetus for states to develop comprehensive state mental health plans containing fundamental changes in adult and children's mental health. Such changes include wide implementation of initiatives toward consumer-driven care, treatment models promoting recovery and resilience, expanded prevention efforts and increased funding for early childhood mental health, and legislation of evidence-based practices.

Funding Challenges

As a result of the growth in mental health expenditures, the resources available to fund child mental health and human services are increasingly strained. Medicaid, the public insurance program for the poor and disabled, funds a significant proportion of child mental health services in the United States. Approximately 37% of children and adolescents 18 years of age and under are enrolled in the Medicaid program. The great majority of these children and youth are poor, underserved children of ethnic minority backgrounds. Children from these populations experience higher levels of stressors, such as poverty, discrimination, immigration, acculturation stress, and exposure to violence and trauma, and are likely to have higher levels of need for services. While children receiving behavioral health services comprise less than 10 of all children on Medicaid, they account for 38% of expenditures. However, the cost of serving these populations of children and adolescents is in contrast to the high cost of the psychosocial morbidity they contend with, including lost productivity and the costs of welfare dependency and institutionalization (6,71,72).

These trends have increased pressures on public child mental health and social service agencies to demonstrate improved clinical and cost-effectiveness, increasingly turning to managed care approaches to finance and organize mental health and social services. Well over half of children who are Medicaid

beneficiaries are under managed care plans (72). However, most managed care methods were developed with adult and private sector populations in mind, and are usually accompanied by the privatization of services. Managed care methodology has been implemented increasingly within Medicaid-funded children's mental health services with the aim of reducing utilization and costs, including approaches such as restrictive formularies, level of care criteria, and restrictive case rates. When applied to public child mental health services, these approaches have often resulted in fragmentation of care and the shifting of the burden of services and cost to the other child-serving agencies and systems, with the potential for significantly increased morbidity (73). Such methodology is also being used to manage services funded by the child welfare system and juvenile justice systems, with significant impact on access and quality of care. However, work continues to address the intersection between managed care methodology and systems-of-care principles (71,74,75).

Mental Health Disparities and Needs of Culturally/Ethnically Diverse Populations

The United States is becoming increasingly culturally and ethnically diverse. More than 36% of all children and youth in the United States are from non-European racial and ethnic backgrounds, and this figure is expected to rise to more than 50% by the year 2030. Children and youth from non-European backgrounds and their families face many adversities, including language barriers, social discrimination, and socioeconomic and educational disparities. The Surgeon General's supplement on culture, race, ethnicity, and mental health (76) has highlighted the serious racial/ethnic disparities in child mental health and social services in our nation, which continues to this day. Today Latino and African-American youth are at higher risk for suicidality than its Caucasian cohorts (77,78).

Children and families from ethnically diverse cultures are distinctly different from those of European origins, with different beliefs, values, normative expectations for development and adaptive behaviors, parenting practices, relationship and family patterns, symptomatic expressions of distress, and explanations of mental illness (77). Consequently, they have specific mental health needs with respect to treatment approaches, modalities, and support services. Studies support the presence of significant racial and ethnic disparities in a number of areas relating to children's mental health, including access to community-based services, accurate diagnostic assessment, access to evidence-based interventions, increasing rates of various forms of psychopathology in some populations, and significantly higher rates of out-of-home placements and institutionalization with equal psychiatric morbidity (particularly in child welfare and juvenile justice). In addition, there is evidence of subtle differences in the metabolism of psychopharmacologic agents in diverse populations, related to both genetic and environmental (dietary) factors (77,79).

There is an increasing consensus that culturally informed approaches to care are needed to address the special mental health needs of diverse populations. This must be accomplished through addressing both clinician-related factors (such as acquiring knowledge, skills, and attitudes that enable them to serve populations different from their own) and system factors (such as reviewing and changing policies and practices that present barriers to diverse populations, staff training around cultural competence, and the recruitment of diverse staff and clinicians for planning service pathways and delivering care). This model also calls for the use of natural strengths and resources in concert with professional services that are protective and support children and families in diverse communities and cultures dealing with emotional disturbance. It also includes the adoption of culturally specific therapeutic modalities (such as use of native healers or cultural mediators), the use of culturally adapted mainstream modalities evaluated with diverse populations, and the appropriate use of language interpreters (77).

The cultural competence model has been operationalized in consensus health and mental health cultural competence standards, such as the AACAP Practice Parameter for Culturally Competent Child Psychiatric Practice (77) and the Center for Mental Health Services standards (80). These standards address cultural adaptations and modifications in clinical processes (such as assessment, treatment planning, case management, and linguistic support) and system processes (such as staff training and development, access protocols, governance of service systems, quality assurance and improvement, and information management). There is beginning evidence that adopting such practices results in improved access to services and retention in treatment (77; also, see Chapter 2.2.1).

Prevention and the Problems of the Very Young

One of the guiding principles of CASSP is to promote early identification for children with emotional disturbances, and therefore communities bear responsibility to assign some of their resources to prevention efforts (3). Examples of vulnerable populations include children experiencing violence, abuse, neglect, or other trauma, and children showing signs of depression or other mental health problems in the school or childcare setting. The integration of mental health services into schools, child welfare, and juvenile justice settings provides early intervention opportunities for children and youth with early symptoms of mental health disorders.

The early childhood population (generally aged 0 to 5 years, defined by their preschool-aged status) is a particularly vulnerable group of children for whom it has been shown that environmental risks can have significant long-term developmental impact, and that early intervention has the potential to be very beneficial over the long term (76). Until CMHS recently started funding of system-of-care projects for 0 to 6 year olds, the early childhood age group had not benefited from system-of-care

reform (81). Since many agencies are involved with young children, the system-of-care model that promotes integrated planning and service strategies is extremely suitable for this age group. System-of-care integrated service strategies may include such activities as providing mental health consultation to Head Start, early intervention, primary care practitioners, community health nurses, and childcare workers; and providing mental health services to adults whose children are at risk of out-of-home placement. Examples of effective preventive approaches include nurse home visiting (82), referral to early intervention services, advocacy for stable placement, support for prenatal care, provision of substance abuse and mental health services and parenting supports to parents of infants at risk for abuse (83), and early mental health services for children at risk for psychiatric disturbance (84).

Barriers to these efforts persist, however, some of which are related to funding and eligibility for services. Mental health agencies may be unable to provide services to children who do not yet meet the full criteria for a mental health diagnosis, and addressing the parents' mental health or substance abuse issues may not be possible if they are uninsured. To address this issue, the state and local funding agencies need to adopt alternative eligibility criteria for services, have contractual agreements with other child-serving agencies that obviate the need for formal diagnosis, or allow the parent to be the recipient of services. For young children who are already showing some early symptoms of disorder, use of a more age-appropriate Diagnostic System for Zero to Three, Revised (DC:0–3R; 85) is more likely to identify conditions making them eligible for services. A crosswalk to ICD-9 diagnoses is needed for billing under the Medicaid system, however. States such as Maine, Florida, Washington, and California have developed crosswalks from DC:0–3 to ICD-9 diagnoses as part of their statewide early childhood plans. The state of Louisiana has developed a statewide program of infant and early childhood services targeted at its child welfare population (83). One barrier is that there are few clinicians trained to diagnose and treat mental health conditions in very young children. States are beginning to invest resources in training to improve the skills of early childhood clinicians.

Challenges in Replication on a Larger Scale

The greatest challenge experienced by system-of-care demonstration programs is how to sustain the model after the grant period ends. Without external funding, the system often reverts to fragmentation and lack of coordination due to the separate funding and organizational structures of mental health, education, juvenile justice, child welfare, developmental disabilities, and substance abuse services. More recent system-of-care projects have benefited from lessons learned as to how to build in sustainability factors early in their projects. Some of the factors supporting sustainability include developing specific targeted outcomes agreed upon by all

stakeholders from the outset, developing effective strategies for tracking and reporting those outcomes, and "social marketing," informing the wider community and legislature of successes of the project in socially meaningful terms (15,86,87).

An additional potentially daunting challenge is how to replicate a small demonstration project on a larger scale that addresses an entire population at a community or state level. It is generally not fiscally viable to apply all aspects of the model on a large scale. For example, regular meetings of interagency teams are costly in terms of personnel time, and may not be needed for children at lower levels of severity. Yet, the systems-level data are not robust enough to guide decision as to which elements of the model to select for the larger population. Thus, states have chosen different elements to implement on a larger scale.

The pediatric collaborative access programs previously described are an example of statewide implementation of one element of systems-of-care design. Some states have implemented statewide versions of wraparound planning programs with intensive in-home services as the front-line intervention. An example of larger scale state implementation to address a particular population need is the Tennessee Centers of Excellence for Children in State Custody. This network of consulting centers located at pediatric medical centers throughout the state is dedicated to address the mental health needs of children in state custody and at-risk of entering custody. They collaborate with regional child welfare agencies in providing case consultation on treatment planning (using the wraparound model), diagnostic evaluation, and pharmacotherapy consultation and services. However, as the centers noted the dearth of child evidence-based practices being delivered to children in custody, they took on the challenge of disseminating key evidence-based practices through statewide trainings, such as trauma-focused cognitive behavioral therapy, PCIT, early infant interventions, and interventions for sexually offending youth. The Centers have been highly successful at directly and indirectly serving thousands of children and youth and were awarded the Silver Service Achievement Award by the American Psychiatric Association (88).

Response to Challenges

There has also been active support for system-of-care reform efforts by professional organizations such as the Academy of Child and Adolescent Psychiatry (AACAP), which in 1994 established a Work Group (now Committee) on Community-Based Systems of Care. The AACAP Committee on Community-Based Systems of Care has developed policy guidelines on relevant topics, including structure of Medicaid managed care programs, training and roles of mental health professionals toward systems of care, outcomes in systems of care, and early childhood systems of care. It has developed tools for assessing service intensity need using a community-based paradigm, and systems-based practice educational materials (38,45,74,75,89).

Systems-of-care reforms have also occurred at the state level. Incremental changes have occurred in many states through national trends, such as managed care Medicaid and the advent of Medicaid waivers that have allowed for innovations and more flexible use of treatment dollars (90). However, reforms associated with managed care Medicaid have not always been positive, as privatization of Medicaid has resulted in some instances in attenuation rather than expansion of appropriate community-based services (44). Some states have legislated very expansive systems reform. For example, Hawaii provides an integrated services model through providing mental health services in schools throughout the state. It has also implemented evidence-based interventions on a wide scale, developing its own classification system for levels of evidence for each treatment modality by diagnosis, and analysis of effective components of each treatment model (91). Hawaii also adopted the Child and Adolescent Service Intensity Instrument (CASII) (92) for statewide use as a treatment planning and outcome measure. The CASII is a tool that provides a uniform procedure for assessment and planning intensity of service need using a community-based systems-of-care paradigm.

A more promising model for funding and service organizations is that proposed by the Affordable Care Act (93). Passed by Congress in 2009, it is a large legislative omnibus bill that attempts to address the United States' chronic problem with lack of insurance coverage for a significant portion of its population. It includes two key provisions that address many challenges posed by systems-of-care reform. First, it includes mental health parity, that is, the equivalent coverage of health and mental health services, a goal that has been pursued by advocates for years. Parity includes coverage going beyond the traditional inpatient–outpatient services and includes coverage of intermediate intensity, community-based services. Furthermore, it promotes the development of "accountable care organizations" which, over time, would be incentivized and reimbursed for clinical outcomes and cost-efficiency, and for a covered population's overall health and function. Such reimbursement and organizational models are totally congruent with the community-based system-of-care model and will hopefully help promote its fuller implementation.

CONCLUSION

The CASSP defined a system-of-care approach to providing mental health and related services to children and adolescents with serious emotional and behavioral disturbances. It has had a major influence on community systems of care through extensive federally funded projects, along with state and national initiatives that have embraced CASSP values. The system-of-care model emphasizes that care should be tailored to the individual needs and strengths of the child and family, culturally competent, coordinated, and integrated, and provided in the most community-based and least restrictive setting that meets their needs. Integrated system-of-care

approaches to service delivery have produced favorable outcomes in reducing use of residential and out-of-state placements and achieving improvements in functional behavior in youth with severe emotional and behavioral disorders who are served in multiple systems. Family and consumer organizations, now strengthened by youth participation, have made substantial contributions to the reform of mental health care in this country.

In many ways, the CASSP and community system-of-care movement and model has been a forerunner for the population health and accountable care models being promoted by health care reformers and within the Affordable Care Act (93). In this vein, children's community mental health has much to share with the rest of health care around consumer-driven, community-based, and preventive approaches, striking a balance between individual and family health and population health.

CHAPTER 6.3.5 ■ TELEPSYCHIATRY WITH CHILDREN AND ADOLESCENTS

KATHLEEN MYERS AND DAVID E. ROTH

OVERVIEW

Telemedicine services are increasingly used to meet the treatment needs of children and adolescents who live in underserved communities (1). The Centers for Medicare and Medicaid Services (CMS) define *telehealth* as the use of telecommunications and information technology (IT) to provide access to health assessment, diagnosis, intervention, consultation, supervision, and information across distance (2). CMS notes that "for purposes of Medicaid, *telemedicine* seeks to improve a patient's health by permitting two-way, real-time interactive communication between the patient, and the physician or the practitioner at the distant site. This electronic communication means the use of interactive telecommunications equipment that includes, at a minimum, audio and video equipment" (3). When telemedicine is used to provide psychiatric—or more generally mental health—services, the terms "telepsychiatry" and "telemental health" (TMH), respectively are used (4–6). As telepsychiatry is not a specialty area but a mode of service delivery, and as the trend nationally is to consider telepsychiatry services equivalent to in-person services, we use the term "provider" to refer to psychiatrists using either mode of service delivery.

DEVELOPMENT OF CHILD AND ADOLESCENT TELEPSYCHIATRY

The Case for Telepsychiatry

The past two decades have brought considerable insights into the early onset of psychopathology, new approaches to pharmacologic treatment, and the development of effective psychotherapies for youth. Yet, most young people with psychiatric disorders do not receive these evidence-based treatments (EBTs), particularly youth living outside of major metropolitan areas (7,8). Furthermore, this discrepancy in access to care is anticipated to grow due to the "aging out effect" of the current psychiatric workforce while fewer medical students choose careers in psychiatry (9,10) and federal mandates have broadened children's eligibility for mental health services (11). According to the United States Bureau of Health Professions, the United States will have only two-thirds of the child and adolescent psychiatrists required to meet needs in 2020 (12).

Federal mandates for mental health care reform have converged with technologic innovations to make telepsychiatry a viable service delivery model for youth who are underserved by traditional models of care. The *Federal Health IT Strategic Plan: 2015–2020* (13) has prioritized the adoption of meaningful health IT with focus on delivery of behavioral health services and reforming payment systems.

The Expansion of Telepsychiatry

As for many other technology-facilitated domains, the practice of telepsychiatry has quickly expanded beyond the intended goal of rectifying disparities for distant communities (14–16). Telepsychiatry services are increasingly offered in diverse settings, including urban and inner city communities (17), mental health centers and other child-serving facilities (15,18,19), correctional settings (20,21), schools (22,23), and the home (24). Telepsychiatry may be a career choice for child and adolescent psychiatrists. For example, those with expertise in treating selected disorders (e.g., obsessive-compulsive disorder [OCD]), cultural/language populations (e.g., Hispanics, Alaska Natives), or relocated groups (e.g., military, refugees, disaster survivors) may seek to export their practices beyond usual constraints of office practice. Other enterprising child and adolescent psychiatrists may enjoy the alternative professional lifestyle that telepsychiatry offers.

THE EVIDENCE-BASED SUPPORTING TELEPSYCHIATRY

The evidence-base supporting telepsychiatry as an effective service-delivery model is well developed with adults and emerging gradually with children and adolescents. Support may be gleaned from reports on the feasibility and acceptability of telepsychiatry with youth, and several outcomes studies, summarized in Table 6.3.5.1, and briefly summarized.

Some providers suggest that telepsychiatry may be especially suited for adolescents who are accustomed to the technology and may respond to the personal space and feeling of control allowed by videoconferencing (22,46) and have decreased concerns about confidentiality as the provider is outside of the local community (27,54).

Multiple studies have demonstrated the feasibility of implementing telepsychiatry services with young people across diverse settings (14–16,19,50,55–59). Youth 2 to 21 years old with a broad range of behavioral health diagnoses and developmental disorders have been evaluated through videoconferencing (15,19,47,49,55). School-aged children comprise the modal age group, and attention-deficit/hyperactivity disorder (ADHD) and depression are the most commonly treated disorders, consistent with in-person care (15,19,25). Children who are uncooperative pose challenges but can be treated with assistance by staff at the patient site. Providers

determine the appropriateness of youth for care via telepsychiatry based on developmental considerations, parents' preferences, supports at the patient site, and the provider's resourcefulness.

Diagnostic assessments have been reliably conducted through videoconferencing (15,42,44,47), including disruptive behavior disorders (28), autism and other developmental disorders (49,52), and psychotic disorders (48). Multiple studies have demonstrated the acceptability to referring primary care providers (PCPs), parents, and youth of delivering services through videoconferencing (15,16,19,37–41,43–45,52). Satisfaction studies demonstrate the ability to develop a therapeutic alliance with youth and families during a virtual visit (60).

TABLE 6.3.5.1

EVIDENCE-BASED SUPPORTING SERVICES TO CHILDREN AND ADOLESCENTS THROUGH VIDEOTELECONFERENCING (VTC)

Citation	Sample	Assessment	Findings
Randomized Controlled Trials			
Nelson et al., 2003 (25)	28 youth (8–14 yrs) with depression	Diagnostic interview and rating scale	VTC and in-person treatment with comparable improvement of depressive symptoms
Storch et al., 2011 (26)	31 youth (age 7–16 yrs) with OCD	ADIS-IV-C/P, CY-BOCS, COIS, MASC, CDI, Satisfaction with services	VTC superior to in-person on all primary outcome measures
Himle et al., 2012 (27)	20 children (8–17 yrs) with Tic Disorders	YGTS, PTQ, CGI-S, CGI-I	VTC and in-person groups show comparable tic reduction
Myers et al., 2015 (28)	223 youth (5.5–12.9 yrs) with ADHD	DISC-IV, CBCL, VADPRS, VADTRS, CIS	Children in the VTC group with greater parent-rated improvement in ADHD-related behaviors than those in augmented PCP group. Teachers reported improvement in ODD and role performance, but not ADHD
Vander Stoep et al., 2017 (29)	223 caregivers of youth (5.5–12.9 yrs) with ADHD	Caregiver distress measures: PHQ-9, PSI, CSQ, FES	Caregivers of children in the VTC group reported greater improvements in distress measures than caregivers in the augmented PCP treatment group.
Rockhill et al., 2016 (30)	223 youth (5.5–12.9 yrs) and providers	DISC-IV, CBCL, VADPRS, telepsychiatrists', and PCP's prescribing patterns	Telepsychiatrists with high fidelity to protocols and more assertive in achieving 50% reduction in ADHD than PCPs
Tse et al., 2015 (31)	37 youth (5.5–12.9 yrs) of the larger 223 participant sample	VADPRS, PHQ-9, CSQ, PSI, FES, Satisfaction	VTC delivery of caregiver training was comparable to in-person delivery in improving children's ADHD symptoms but not caregivers' distress
Xie et al., 2013 (32)	22 children (6–14 yrs) with behavioral	PCQ-CA, VADPRS, CGAS	Parent training through VTC was as effective as in-person

	disorders		
Pre-Post or Comparison Studies			
Glueckauf et al., 2002 (33)	22 adolescents (15.4 yrs) 36 parents	SSRS, WAI, issue-specific measures of family problems, adherence to treatment	Comparable improvement for intervention through VTC vs. in-person vs. speakerphone; therapeutic alliance high but teens rated alliance lower in VTC
Fox et al., 2008 (34)	190 youth (12–19 yrs) in detention	GAS	Improvement in the rate of attainment of goals associated with family relations and personality/behavior
Yellowlees et al., 2008 (35)	41 children in an e-mental health program	CBCL	A retrospective assessment of 3-mo outcomes found improvements in selected Domains of the CBCL
Reese et al., 2012 (36)	8 children (M = 7.6 yrs)	ADHD	Group Triple P Positive Parenting Program via VTC associated with improved child behavior and decreased parent distress
Satisfaction Studies			
Blackmon et al., 1997 (37)	43 children (2–15 yrs)	12-item Telemedicine Consultation Evaluation	All children and 98% of parents report satisfaction equal to in-person care
Elford et al., 2001 (38)	30 children (4–16 yrs)	Satisfaction Questionnaire	Psychiatrists, children, teens, parents, endorsed high satisfaction with VTC
Kopel et al., 2001 (39)	136 participants (age not specified—refers to “young person”)	Satisfaction Questionnaire	High satisfaction by families and rural health workers in New South Wales, Australia
Greenberg et al., 2006 (40)	35 PCPs, 12 caregivers (mean age of children: 9.3 yrs)	Focus groups with PCPs, interviews with caregivers	PCP and caregiver satisfaction with VTC, limitations of local supports
Hilty et al., 2006 (41)	15 PCPs (400 children and adults)	PCP Satisfaction Survey	PCP satisfaction was high and increased over time
Myers et al., 2007 (19)	172 patients (2–21 yrs) and 387 visits	11-item Psychiatrist Satisfaction Survey	High satisfaction of PCPs, pediatricians more satisfied than family physicians
Myers et al., 2008 (16)	172 patients (2–21 yrs) and 387 visits	12-item Parent Satisfaction Survey	High satisfaction and increasing with return visits; lower satisfaction with care for teens than for children
Myers et al., 2010 (42)	701 patients (7–19 yrs) and 190 PCPs	Collection of patient demographics and diagnoses	VTC with youth is feasible and acceptable; services vary with telepsychiatrists’ practices
Pakyurek et al., 2010 (43)	5 case studies of youth in primary care	Effectiveness of VTC in treating a range of problems	VTC might be superior to in-person for selected groups
Lau et al., 2011 (44)	45 youth (3–17 yrs)	Description of patients referred for consultation, reason	VTC consultation provides diagnostic and treatment clarifications to a variety of children

		for consultation, treatment recommendations	
Descriptive and Service Utilization			
Myers et al., 2004 (15)	159 youth (3–18 yrs)	Comparison VTC vs. in-person care on demographic and process variables	VTC patients were representative of in-person outpatients demographically, clinically, and by reimbursement
Myers et al., 2006 (21)	115 incarcerated youth (14–18 yrs)	11-item Teen Satisfaction Survey, medication management	Describes large series of incarcerated youth, including medication management
Jacob et al., 2012 (45)	15 children (4–18 yrs)	12-item Parent Satisfaction Survey	Patient satisfaction high and PCPs found recommendations helpful.
Nelson and Bui 2012 (46)	22 youth (M = 9.3 yrs)	Chart review	No factor inherent to the VC delivery mechanism impeded adherence to national ADHD guidelines
Diagnostic Validity			
Elford et al., 2000 (47)	25 children (4–16 yrs) with various diagnoses	Diagnostic interviews	96% concordance between VTC and in-person evaluations; comparable satisfaction
Stain et al., 2011 (48)	11 patients (14–30 yrs)	Diagnostic Interview for Psychosis, DIP	Strong correlation of assessments done VTC vs in-person
Reese et al., 2013 (49)	21 children (3–5 yrs)	ADOS—Module 1, ADI-R, Parent Satisfaction	VTC comparable to in-person for diagnostic accuracy, observations, parents' report of symptoms, and satisfaction
Other Relevant Studies			
Boydell et al., 2007 (50)	100 youth (2–17 yrs)	Chart review and interviews with case managers	Pros and cons of adherence
Shaikh et al., 2008 (51)	99 youth (1–17 yrs)	Review of patient medical records	VTC consultations associated with changes to diagnoses; repeated VTC consultations associated with improved weight-related status
Szeftel et al., 2012 (52)	45 patients (31 under 18 yrs) with developmental disabilities	Chart review—medication changes, frequency of appointments, diagnostic changes, symptom severity and improvement	VTC led to change of psychiatric diagnoses for 70% of patients, changed medication for 82% of patients, helped PCPs with treatment
Davis et al., 2013 (53)	58 youth (5–11 yrs)	Body mass index, 24-hr dietary recall, ActiGraph, CBCL, BPFAS	Two groups included and showed comparable improvements in BMI, nutrition, physical activity, and primary outcomes

ADI-R, Autism Diagnostic Interview—Revised; ADIS-IV-C/P, Anxiety Disorders Interview Schedule—Child/Parent Version; ADHD, attention-deficit/hyperactivity disorder; ADIS-IV-C/P, Anxiety Disorders Interview Scale—DSM-IV-Parent and Child Versions; ADOS, Autism Diagnostic Observation Scale; BPFAS, Behavioral Pediatrics Feeding Assessment Scale; CBCL, Child Behavior Checklist; CDI, Children's Depression Inventory; CGAS, Clinical Global Assessment Scale; CGI-I, Clinical Global Impressions of Improvement Scale; CGI-S, Clinical Global Impressions of Severity Scale; CIS,

Columbia Impairment Scale; COIS, Child Obsessive Compulsive Impact Scale; CSQ, Caregiver Strain Questionnaire; CY-BOCS, Child Yale-Brown Obsessive Compulsive Scale; DIP, Diagnostic Interview for Psychosis; DISC-IV, Diagnostic Interview Scale for Children for DSM-IV; BMI, body mass index; FES, Family Empowerment Scale; GAS, Goal Attainment Scale; MASC, Multi-dimensional Anxiety Scale for Children; PCQ-CA, Parent Child Relationship Questionnaire; PTQ, Parent Tic Questionnaire; PCP, primary care provider; PHQ-9: Patient Health Questionnaire-9 Items; PSI: Parenting Stress Index; OCD: obsessive compulsive disorder; ODD: oppositional defiant disorder; SSRS, Social Skills Rating System (teen functioning); VADPRS, Vanderbilt ADHD Parent Rating Scale; VADTRS, Vanderbilt ADHD Teacher Rating Scale; VTC, videoteleconferencing; WAI, Working Alliance Inventory; YGTS, Yale Global Tic Severity Scale.

The delivery of pharmacotherapy through telepsychiatry has been described with youth in schools (61), mental health centers and daycare (17), outpatient settings (15,16,19,42), and juvenile justice facilities (20,21). One recent large community-based randomized trial provides solid evidence of the effectiveness of short- term pharmacotherapy for ADHD delivered by child and adolescent providers compared to treatment in primary care (28). Further, providers demonstrated good adherence to guideline-based pharmacotherapy (30).

There is a strong literature supporting the feasibility of conducting psychotherapy with adults through videoconferencing (62–66) and a developing literature supporting outcomes that are comparable to care delivered in-person (63). Most studies of psychotherapy conducted with young people have been descriptive (14,58,65). Nelson and Patton identified 10 psychotherapy studies (65). Intervention approaches varied in focus on the youth or the parent and ranged from feasibility trials to pre-post designs, and a few controlled trials. Findings were overall positive related to feasibility, satisfaction, and outcomes. This review also identified several case reports and small pilot studies on psychosomatic medicine, addressing mental health approaches for youth with acute and chronic medical conditions, including obesity (51,53).

Several randomized trials of psychotherapy are noteworthy. Nelson et al. found comparable reductions for childhood depressive symptoms treated with eight sessions of cognitive-behavioral therapy (CBT) delivered through videoconferencing versus in-person (25). Storch et al. tested the effectiveness of treatment for OCD and found superior outcomes to children treated in-person (26). The behavioral treatment of tics through telepsychiatry has been found to be comparable to in-person treatment (27). Four small randomized controlled trials have demonstrated the effectiveness of providing family interventions (31–33,36). A recent case report describes family-based interventions for eating disorders (67).

LEGAL, REGULATORY, AND ETHICAL ISSUES

Licensure is a complex issue. The 10th Amendment of the United States Constitution grants the individual States control over establishing and enforcing licensure requirements for health care professionals (68). The potential of telepsychiatry to

deliver care across boundaries has challenged the limits of the state-based licensure system and stimulated discussion of alternative approaches such as national licensure, specific telemedicine licensure, and reciprocity of licensure (69). However, movement on this issue is slow.

National organizations differ in their policies and guidelines. While the Federation of State Medical Boards requires physicians to be licensed in the state where the patient is located, it supports the creation of an "interstate compact" licensure system (70), while the American Medical Association supports the existing state-based licensure system. The American Telemedicine Association (ATA) guidelines recommend that health professionals comply with all laws and regulations in both the patient's and provider's sites (71). Some states allow reciprocity of license to neighboring states (72). Providers should check with the requirements of the state medical boards where they plan to deliver services.

Location of Telepsychiatry Services vary by state with respect to the physical location of both the patient and the provider. Generally approved sites include medical and mental health facilities. More variably approved are assisted living facilities, schools, other community sites, and the home. Special approvals may be negotiated with payers. There is a trend toward broadening state and federal guidelines for reimbursement for services delivered to schools and removing the requirement of a defined distance from available on-site services (73). Several states require a "presenter," or "telepresenter," to accompany the patient (73,74).

Authentication of the parties involved in a telepsychiatry encounter ensures accuracy of service delivery and protects against fraud. During the initial encounter with a patient, the provider should collect identifying information about the patient, including location (75). If the patient site is a health care facility, the staff may verify the patient's identity. Typically, providers begin the initial session by stating their name, credentials, and location (city and state). Such information is included in the documentation.

Privacy and Security must comply with the Health Insurance Portability and Accountability Act of 1996 (HIPAA) (76). Compliance is not achieved by following a simple checklist of technical requirements. Software vendors enter into a Business Associate Agreement with HIPAA attesting their due diligence to protect patient privacy and data and agree to an audit of patient health information if a security breach occurs. Potential providers should determine whether a technology vendor is compliant with HIPAA requirements and check relevant state privacy laws that may have more stringent requirements.

Informed Consent also involves a process that varies by state regarding the need for specific consent to receive services through videoconferencing (5). Some elements for consent include: confidentiality and the limits to confidentiality when using electronic communications; potential for technical failure, emergency plans; documentation, recording, and storage of information; protocols for coordination of

care with other professionals and contact between sessions; and conditions under which services are terminated and a referral for in-person care made (77).

Emergency Care is a highly desired service for underserved communities. Local civil commitment laws, duty to warn/protect requirements, and mandated reporting of child endangerment vary by jurisdiction. Providers and staff prepare a crisis plan with the family and staff share the plan with other members of the patient's system of care. These crisis procedures are discussed at the initial encounter or as part of informed consent (78). The role of the parent in emergency service planning must consider age of consent.

Ethical Issues in telepsychiatry parallel issues encountered in traditional in-person services. The core ethical goal to protect the patient remains paramount (75,79–81).

TECHNICAL ASPECTS OF TELEPSYCHIATRY

Telecommunications technology refers to the technical methods, or protocols, used to establish a synchronous connection (82,83). The visual and auditory quality of the data must be good enough for the provider and patient to feel it has been an authentic medical experience. Selecting the best technology can be a daunting process because the technology is rapidly changing and many vendors offer a wide range of commercial plans.

Start the selection process by prioritizing the features and functions needed to deliver the clinical services. Second, consider the budget, staffing resources, and startup timetable. Third, decide if the program needs to connect to an existing videoconferencing network. The clinical goals of the program should influence the selection of technology, as specific clinical services and populations may require different technologies. For example, diagnosing genetic and neurodevelopmental disorders may require higher-resolution video to see cutaneous abnormalities while group therapy may require multiple microphones, breakout group, and chat functions. Financial factors related to software subscriptions, hardware purchases, Internet service provider (ISP) contracts, space, and staffing play an important role in the selection of telecommunication technology. The provider and remote site staff must realistically consider their technical and financial ability to operate, and maintain the technology. Finally, deciding to extend an existing videoconferencing system or replace it with a cloud-based system will restrict the decision to a smaller number of vendors and technology options. Providers can learn more about buying technology from these commercial vendors and software companies at the ATA's Resource Center & Buyer's Guide website (84).

If the program will build upon an older system, it is likely a standards-based applications/platform, sometimes referred to as "legacy hardware." These proprietary systems offer the highest quality of audio and video, as well as the most

stable data connection, giving participants the most life-like or "telepresence" experience. They transmit data over digital subscriber lines (DSL). This telephone company-based end-user connection transmits secure, point-to-point, high-bandwidth ($\geq$1.5 mbps), high-definition video and audio signals over satellite or fiberoptic systems. Typical DSL broadband capacities are 1.5, 3, 5, 10, 12 mbps, which seem small compared to residential ISP plans that offer 300 mbps, but because these systems use a static Internet protocol (IP), they are guaranteed this speed at all times and the connection is more stable than the dynamic IPs used in residential connections. These systems also offer many sophisticated features including the ability to zoom and pan/tilt cameras at both sites, connect to medical devices like stethoscopes, and connect to multiple microphones, and large (and multiple) monitor systems. These features enable the provider to closely examine the patient and control how he/she view the participants in multipoint conferencing. These systems require technical support to operate with other legacy systems. Despite their superior functioning, standards-based systems are predominantly used in medical centers or other large organizations because they require a considerable initial investment and high costs for maintenance, technical staff, and related IT infrastructure.

Consumer-based software platforms transmit data over the Internet and the consumer interface software run on personal computers, tablets, and smartphones. Subscriptions to these cloud-based services are sold based on the number of users or accounts, ranging from free single account packages to enterprise-level subscriptions with hundreds of accounts. Enterprise-level contracts often include an option to purchase the software that would allow the consumer to host the service on its own server. Local hosting can greatly improve the telepresence quality of the videoconference. Software vendors who advertise telehealth solutions must provide appropriate software encryption and sign Business Associate Agreements to comply with HIPAA regulations.

Recent advances in both hardware and software signal compression has enabled these Internet-based systems to deliver the high-quality video and audio signals necessary for clinical work. They are highly flexible, adaptable, and consumer friendly, enabling rapid deployment to a variety of settings with minimal training, startup costs, and fixed costs. Interested purchasers should review their options on unbiased websites, such as the ATA website (http://www.americantelemed.org).

There are disadvantages to conducting telepsychiatry sessions over cloud-based applications that utilize the Internet. The foremost is the highly variable quality and speed of the connection, which impacts the quality of streaming audio and video. The connection quality and speed can be affected by many factors including nearby Internet traffic (for cable–modem connections), inclement weather, network failures, local electrical device interference to WiFi signals, and *Intranet* network traffic at the origination and destination sites. Other disadvantages to these cloud-based platforms include variable customer support from the vendor, a greater chance that

end users will inadvertently alter the hardware or software, limited ability to connect peripheral devices such as a stethoscope, and usually no ability to control the camera at the patient's site. They usually do not connect to legacy videoconferencing devices installed in many health care centers, schools, and other organizations. While many systems provide adequate video and audio quality, the purchase of an external camera and microphone (Figure 6.3.5.1) can considerably improve quality of the interaction.

FIGURE 6.3.5.1. External USB cameras improve picture and sound. Photograph courtesy of Dr. Roth, author.

In summary, choosing the best videoconferencing platform is a complicated decision. Providers must consider their budget for initial and ongoing costs, the available bandwidth at all sites, the technical sophistication of users, access to technical support, and the need to control the remote equipment. Other helpful resources are available from the National Telehealth Technology Assessment Resource Center (http://www.telehealthtechnology.org) and the ATA (http://www.americantelemed.org).

ESTABLISHING A TELEPSYCHIATRY PRACTICE

The following is a brief overview of issues for potential providers to address in determining whether telepsychiatry is relevant to their clinical practice. More

information can be found through the ATA (http://www.americantelemed.org) and the National Telehealth Technology Assessment Resource Center (http://www.telehealthtechnology.org).

Feasibility and Sustainability of a Telepsychiatry Practice

Telepsychiatry is poised to play an increasingly important role within pediatric health care systems. Services to primary care settings are anticipated to increase with national and state initiatives around the patient-centered medical home (85). Telepsychiatry is one strategy for incorporating mental health treatment into primary care settings and has the added potential for increasing the PCPs' skills in caring for mental health problems.

Determining the feasibility of a telepsychiatry service is based on an accurate needs assessment that identifies the mental health needs of the patient site and determines whether the proposed service is likely to meet those needs and to complement existing services. It is helpful to visit the patient site and meet with local stakeholders for services collaborative problem solving.

Sustainability of a telepsychiatry service is determined within the context of the community's needs. For example, a medical center may not benefit directly from a telepsychiatry service, but there could be financial benefit to the institution if emergency room services decrease. The community as a whole may also benefit from lower expenses related to correctional or educational services for youth. With technology costs lowering and an increasing number of insurers reimbursing telepsychiatry services, sustaining such a service without outside funding is becoming more possible. Telepsychiatry providers are encouraged to review information at the Center for Medicare and Medicaid Services website (www.cms.gov) and the ATA website (http://www.americantelemed.org) prior to any billing to determine any jurisdiction-specific guidelines.

Patient Population and Models of Care

The patients to be served should be identified by the patient site. Patient inclusion and exclusion criteria are based upon judgment of the provider, and resources at the patient site, including the site's ability to attend to acutely suicidal or agitated patients. Exclusion criteria may include factors such as youth without accompanying guardians, patients without a PCP, or patients with a PCP who is uncomfortable resuming care for psychiatric patients. Several models of care have been used to provide telepsychiatry services, including consultation, direct care, or collaboration with another provider (1,86,87). Some programs have developed specific models for consultation to primary care (19,35), including one that moves flexibly between consultation and direct care (42). When ongoing direct care is offered via

telepsychiatry, a PCP should be identified to provide care when the provider is unavailable and to resume care when the patient becomes stable.

Private Practice Options

Telepsychiatry programs are no longer solely the purview of major medical centers. Private practice providers have several options (88,89). Those preferring more practice support may choose to work for a company offering a virtual group practice with a spectrum of services ranging from models that provide a high level of structure, including management of the videoconferencing technology and patient referrals, while contracting with providers for the clinical service (83). Providers who are confident with technology and referral sources may contract with a company that simply provides a secure web-based connection (88,89). The independent provider is then responsible for performing the needs assessment to determine whether the telepsychiatry service is needed, feasible, and sustainable, as well as to establish protocols addressing clinical, business, and regulatory issues (88,89).

THROUGH THE LOOKING GLASS: OVERCOMING THE CHALLENGES INHERENT IN CREATING AUTHENTIC PROVIDER–PATIENT RELATIONSHIPS DURING TELEPSYCHIATRY

Like an actor stepping onto the stage, providers must immediately engage patients' attention and convince them that they are trustworthy, competent, empathic, and will be responsive to their needs (90). Providers who naturally create good rapport are instinctually communicating verbally as well as nonverbally. The importance of sending and observing nonverbal communication cannot be overstated; because over two-thirds of communicated meaning can be attributed to nonverbal messages (91). Clear communication is an integral part of good bedside manner and is the key to building and maintaining therapeutic relationships. It is often not what is said, but how it is said, that matters most to patients (92,93). For the purpose of this chapter, nonverbal communication is defined as everything except for the contextual meaning of the spoken words, including: the nature, location, and decoration of the room, the provider's physical appearance, distance between participants, body movements, posture, gestures, facial expressions, eye contact, touch, and the tone, pacing, and volume of the provider's voice.

The nonverbal communication to consider during telepsychiatry includes:

- The nature, location, and decoration of the room
- Physical appearance

- Individuals' distance from one another
- Body movements, posture, and gestures
- Facial expressions
- Touching the other person
- The tone, rate, and volume of the provider's voice

Communicating during telepsychiatry differs from communicating in person. Cameras, microphones, and speakers alter voice and appearance and flatten emotional expressions. Most providers experienced in telepsychiatry slightly enhance their communication style to establish a therapeutic relationship. Many of these enhancements are techniques used by newscasters and actors to communicate authenticity to their audiences.

Providers must command a working knowledge of these nonverbal communication restrictions. The first nonverbal communication is patients' view of the provider as the camera frame limits patients' ability to see the provider and his/her nonverbal communications. They have less access to environmental information to shape their perception of the provider as trustworthy, competent, and empathic. The provider's physical appearance, grooming, uniform/dress, and interactions become a more significant part of how patients' make a first impression (60). If providers' nonverbal communication does not support their verbal communication, the provider seems odd or insincere (94). This weakens the provider–patient relationship (95).

Telehealth technology affects the provider's ability to:

- See the patient
- Be seen by the patient
- Be heard and understood
- Make gestures
- Maintain eye contact
- Touch
- Smell
- Demonstrate usual good bedside manner

Erect and open body posture communicates to patients that the provider is a confident, nonjudgmental, and trustworthy authority figure (96) who is paying attention to their needs (97). Moving toward or away from the camera approximates the effect of interpersonal space during in-person sessions. For example, moving slightly closer to the camera communicates more interest or attention. If the patient seems defensive, moving slightly away from the camera conveys the perception of giving the patient more distance. The picture-in-picture function on the monitor helps providers to monitor how their image is projected and to stay within the frame (Figure 6.3.5.2).

As patients can only see facial expressions, gestures, movements, and activities that fall within the camera frame, providers must replace large gestures with smaller ones that are more easily seen (98). Common gestures like outstretched arms can be replaced with hand gestures or emotionally congruent facial expressions (99). Hand gestures like waving and the thumbs-up sign can also replace culturally relevant handshakes and fist-bumps that are lost in telehealth.
FIGURE 6.3.5.2. Picture-in-picture function monitors screen image. Photograph courtesy of Dr. Roth, author.

The provider's tone of voice affects the relationship (100). Without sounding robotic, the provider must sound honest, compassionate and intelligent while speaking slowly, loudly, and clearly enough to be easily heard and understood through the microphone. Many novice providers speak robotically due to performance anxiety or distractions by the electronics (e.g., a medical record that is simultaneously projected onto a monitor during the session). Providers may modulate the pitch of their voice slightly to avoid sounding anxious or robotic, but the challenge then is to avoid seeming theatric. Smiling while speaking makes the provider sound warm and approachable. Placing a smiley face sticker next to the camera is a good reminder for those who often look or sound too serious.

Encouraging patients to speak more is associated with feeling that their needs are fulfilled (101). There is a very brief transmission delay during videoconferencing that affects communication. Therefore, pauses and turn-taking are important for the provider to manage. Giving the patient an extra moment to reply in conversation may seem like a long pause but will replicate a normal pause during in-person

conversation. During multi-center sessions, the provider may need to allow for even longer pauses.

Due to the slight audio transmission delay, verbal encouragers (e.g., yes, tell me more, go on) are more difficult to use during telepsychiatry. If the participant has already resumed speaking, he or she stops speaking to listen to the encourager, thereby interfering with communication. Therefore, experienced providers frequently use gestures, such as the thumbs-up gesture, to facilitate the reciprocal exchange of information while maintaining engagement and without interrupting the speaker. The other approach is to nod and smile. After thousands of telepsychiatry sessions, the authors suggest the most important nonverbal rapport-building strategy is to periodically nod and smile while the patient is talking, thereby indicating that the provider is listening and encouraging the patient to continue. Consider placing a sticky note that says, “Nod and smile!” on the monitor until this becomes natural.

OPTIMIZING THE TELEPSYCHIATRY EXPERIENCE

Room Selection

Optimizing the telepsychiatry experience begins with appropriate room selection. In telepsychiatry, the camera is turned on and—boom! The provider is suddenly meeting with the patient. There is no grand hospital architecture, professional décor, or staff interactions to mentally prepare the patient for the clinical encounter. To further complicate matters, the patient site may be a home, school, or another provider’s office—all settings the provider cannot control. It is up to the provider to make it an authentic clinical experience. To start, attention is given to selecting, arranging, and appointing the rooms at both the patient and provider sites. Telepsychiatry providers often work with a wide range of rooms, but with the right setup, sessions can be successfully conducted in classrooms, conference rooms, treatment rooms, offices, living rooms, and bedrooms. After the room at the patient’s site is selected, it should be appointed to support videoconferences, accommodate the routine number of participants, and maximize participants’ focus during the session.

Room selection should ensure that:

- Everyone feels comfortable
- Distractions are minimized
- Everyone is able to see each other
- Everyone is able to hear each other
- The room maintains visual and auditory privacy
- Room size accommodates the clinical encounter
- Décor minimizes camera distortion

Power and Network

One of the most important considerations in room selection for sites using cloud videoconferencing is proximity to the WiFi router to maintain a strong Internet connection. If connecting through a computer, it should be plugged into the router with an Ethernet cable to provide the strongest video and auditory signal. Most software automatically downgrades the picture and sound to match the worst connection, so one slow site compromises the experience for everyone involved. Plugging the router, modem, computer, and monitor(s) into a combination surge protector and battery backup will ensure that the connection will not drop if there is a momentary electrical surge or loss of power.

Room Set-Up

Selecting a room with a camera-friendly color scheme makes it easier for the camera to focus on the participant instead of the background. The camera should be focused on a wall that is painted a soft neutral shade to help the participant's image stand out from the wall. Decorations and patterns that are small, intricate, highly detailed, or cluttered may distort video images and trick the camera into focusing on the background (Figure 6.3.5.3). There should be nothing directly behind the participant's head because the camera's poor depth projection makes them appear to grow out of the participant's head. The decorations in the provider's room should be minimal and professional, reflecting the services delivered.

Cameras

Camera placement will determine framing of the video image. Framing determines who and what is visible on the screen, as well as accurate observation of participants' presentation. Poor placement may detract from the interaction and ultimately whether the clinical experience seems authentic, as shown in Figure 6.3.5.4. Cameras should be positioned at a sufficient distance from the patient to allow visualization of the child's motor abilities and activities but also to allow assessment of facial features and affect.

Participants naturally look at the monitor to relate to one another during videoconferencing. However, the camera is typically placed on top of the screen so that participants appear to be gazing downward. Provider eye contact is significantly related to patients' perceptions of the provider's connectedness and empathy (102). Therefore, providers' cameras should be directly in front of them, positioned at eye level, as shown in Figure 6.3.5.5. This positioning makes the provider gaze toward the camera when looking at the screen. Assessing eye contact is an essential component of the developmental evaluation of children and establishing a therapeutic

alliance, particularly during a videoconferencing encounter when there is decreased access to other nonverbal means of communication. The provider should determine whether apparent decreased eye contact represents a technical limitation or a clinical impairment.

FIGURE 6.3.5.3. Cluttered background and suboptimal lighting interfere with camera's functioning. Photograph courtesy of Dr. Roth, author.

If a single participant is using a phone or a tablet, it should be positioned in vertical/portrait orientation. This improves the eye contact between participants because the other participant's eyes are closer to the camera. If the device needs to capture two or more people in the frame, turning the device horizontal/landscape will often create a larger frame that encompasses more of the room.

Medical providers spend 30% of a clinical visit gazing at the electronic medical record (EMR) (103). If the EMR is used during the session and can be projected onto the screen, it should be placed in a vertical window above or below the participants' images. This causes the provider to constantly nod up and down in a positive and affirmative manner when glancing at the participant's EMR. By contrast, if the EMR window were placed lateral to the participant images, the provider would be constantly making negative, head-shaking gestures during the session. Telepsychiatry providers should minimize the time spent looking at the EMR in order to maintain eye contact and rapport with the patient, even if this means charting very little during the session.

FIGURE 6.3.5.4. Poor framing of video image impedes authentic patient–provider relationship. Photograph courtesy of Dr. Roth, author.

FIGURE 6.3.5.5. Approximate eye contact with proper camera placement. Photograph courtesy of Dr. Roth, author.

Lighting

Lighting affects quality of the videoconferencing session (98). Cameras need more light than human eyes to produce a clear image. An insufficiently illuminated room prevents participants from seeing each other clearly, detecting nonverbal communication, identifying physical signs and symptoms, and detracts from the authenticity of the experience. Backlighting should be avoided. This occurs when a bright light comes from behind the person, such as when seated in front of a window or bright light. The person becomes silhouetted. This issue should be considered early in room selection when the position of the camera is determined. Copious indirect lighting, such as floor lamps that bounce light off the ceiling, is the key to a good lighting plan. It looks natural, softer, and avoids glare or shadows. Removing or covering reflective surfaces that cause glare also helps to optimize the video image.

Privacy

Common sense cures most privacy problems. This is handled at two levels. At the software level, most commercial telehealth vendors advertise whether they meet HIPAA standards. The second aspect of privacy is participation. Sites must ensure that they can restrict access to the videoconferencing room, as well as others' ability to view the session. This may be challenging in very small communities with limited room availability or when providing consultation to a small emergency room. Home-based services provide particular challenges as a space must be large enough to include all participants but not accessible to non-participating family members. Family sessions may be best accommodated in the kitchen or family room, but these are high-traffic areas. Individual sessions, and some parent–child sessions, may be conducted away from other family in a bedroom, office, or porch.

Audio privacy may be the largest obstacle to privacy. If the patient site is a clinical examination room it will already have been soundproofed. However, many times the videoconferencing equipment is set up in a conference room or private office with inadequate soundproofing. Sound privacy may be determined by asking a staff to stand outside the doors and windows during a sham session and report on audibility.

Ways to improve audio privacy

- Close windows
- Block gaps below doors
- Place a white noise machine outside and beside the door to the telehealth room.
- Put carpet or an area rug on the floor
- Add pillows to couches, curtains on windows, and/or tapestries on walls to absorb sound
- When remodeling, use decoupling soundproofing construction techniques
- Consider using a headset microphone

Audio Quality: Distractions and Audio Signal

Audio privacy and comfort also relate to ambient noise that varies across rooms. The microphones are sensitive and amplify sound affecting the volume of participants' speech and quality of the sessions. Common disturbing background sounds are printers, air conditioners, fans, intercoms, animals, lawn equipment, and outside traffic. Rooms should be selected to minimize these common interfering sounds. However, most rooms are not perfectly quiet and the provider should work with staff at the patient site to implement strategies to decrease background noise. If services are provided in the home uninvolved individuals should be forewarned to stay out of the room during the session.

Audio communication depends on the microphone and speakers. Computers, tablets, and phones often have built in microphones and speakers that are adequate for clinical service. However, if providers can add a peripheral device to their system, a quality microphone can filter out background noise and improve communication. If the provider is the only person in the room, he or she could use a headset microphone that eliminates most background sounds, and ensures that participants' voices are not overheard.

Finally, it is important to have a backup plan in case the audio connection fails. Usually, a conference speakerphone can be used to provide an adequate connection while not seriously compromising synchrony with the video signal. The audio device in the videoconference software must be muted to avoid echoes and feedback due to running two microphones simultaneously.

Approaches to minimizing background noise include:

- Close windows and doors
- Turn down/off window and portable air conditioners, fans
- Do not to run other equipment (e.g., printers, fax machines, dishwashers)
- Turn off electronics
- Keep pets out of the room
- Encourage the patient site to only allow quiet toys without multiple parts, such as foam blocks, books, markers, action figures, and dolls

SUMMARY

Effective telepsychiatry providers are able to create authentic provider–patient relationships by augmenting the provider's good bedside manner with a few acting, news casting, and venue staging skills. When these skills, strategies, and techniques are put together well, they make telepsychiatry look easy and the interactions feel authentic to both patients and providers. With sufficient practice, providers can be as effective and comfortable treating patients via telehealth technology as they are in other clinical venues. Additional resources on optimizing the telepsychiatry session are available through the Telemental Health Guide (www.telepsychiatryguide.org), the Telehealth Resource Centers (www.telehealthresourcecenter.org), and ATA (www.americantelemed.org).

INTERVENTIONS

Interventions provided via telepsychiatry to children and adolescents should be consistent with clinical practice guidelines established by the American Academy of Child and Adolescent Psychiatry (AACAP) for specific psychiatric disorders and

treatments (104) and should follow guidelines established for TMH service delivery (75,79,105).

The psychiatric assessment of children and adolescents includes spending some time interviewing the youth alone. Older children with good impulse control, adequate verbal skills, and the ability to separate can be interviewed alone. Younger, developmentally impaired or impulsive youth need a modified approach. Traditional play sessions may be challenging. The child may be observed interacting with staff in a structured or free play session. Some limited play with the child may be possible over the telemonitor (e.g., drawing pictures and then discussing them or developing a play scenario with puppets).

Preschoolers should be observed in developmentally appropriate interactions with their parent(s) and, if indicated, with an unfamiliar adult, perhaps a staff member. Many young children will engage in direct interaction with the provider, such as distinguishing colors, pointing to body parts, singing the alphabet, or relating a story.

Pharmacotherapy is a highly desired service. Approaches to medication management depend on the model of care (17,19,106,107). Regardless of the model used, it is important to maintain communication with the PCP about the treatment. Medications that are not regulated by the Drug Enforcement Administration (DEA) can be prescribed consistent with methods used in traditional practice. However, federal legislation regarding the prescription of controlled substances through videoconferencing has implications for telepsychiatry, especially for the treatment of children with ADHD. The Ryan Haight Online Pharmacy Consumer Protection Act of 2008 (108) was designed to expunge illegitimate online pharmacies that dispensed controlled substances without contact with the individual and without physician oversight. The Act placed certain restrictions around the practice of "prescribing by means of the internet." While the Act specifically designates that telemedicine is an exception to the Act, it technically requires that providers conduct at least one face-to-face evaluation of the patient prior to prescribing a controlled substance via telemedicine. Alternatively, patients being treated by and physically located in a hospital or clinic registered with the DEA in the presence of a DEA-registered practitioner may be prescribed controlled substances via telemedicine. The letter of this legislation is difficult to follow and severely dilutes the value of telepsychiatry practice. However, the DEA recently noted that it does not intend to interfere with the legitimate prescribing of controlled substances during telemedicine practice (109). It has further promised to promulgate future rules around telemedicine prescribing and to establish a special telemedicine registration. Unfortunately, these provisions have been left incomplete since 2008. Several states have enacted legislation to allow the prescription of controlled substances through telemedicine practice, particularly for telepsychiatry. Providers should carefully review both federal and state guidelines in establishing their telepractice regarding the

prescription of controlled substances and act in the best interests of their patients.

Tracking vital signs, height and weight, obtaining rating scales, monitoring physiologic status, and assessing adverse effects are accomplished with coordination from staff at the patient site. Abnormal movements due to antipsychotic medications can be assessed remotely by the provider using the Abnormal Involuntary Movement Scale (110) or a nurse can be trained to complete the scale in person.

An important aspect of medication management is providing care or assisting staff between sessions. Protocols are needed to provide families clear directions for requesting refills, asking questions, and reporting adverse effects.

Psychotherapy is increasingly provided to families and youth through various devices in multiple settings. In addition to translating evidence-based psychotherapies to the videoconferencing venue, particular attention to cultural context is needed as providers in urban/suburban areas and families in rural areas often differ in their cultural heritage (111). Adolescents' increasing access to mobile device–based (m-health) applications, particularly smart phones, presents a promising opportunity to reach youth in need of services. As of 2014, 58% of the United States population owned a smartphone (112). In underserved populations, rates are 47% for low-income households, 43% for rural areas, and are *higher* for minorities than Caucasians. Moreover, the vast majority of the population will likely own smartphones in the near future as 90% currently own a cell phone and the percentage of smartphones versus traditional cell phones has been rising (112,113). These data suggest that smartphones will be increasingly a convenient medium for reaching individuals of all ethnicities, incomes, and geographic regions. Moreover, m-health applications have a number of capabilities associated with successful interventions utilizing communication technology, including: scheduled reminders to engage in therapeutic exercises (114); point of performance support (115); individually tailored information (116,117); real-time symptom assessment (118); and attractiveness to youth through increased sense of autonomy (119). Such technologic advances may change the face of psychotherapy for both distant and local communities.

EVALUATING A TELEPSYCHIATRY SERVICE

As the demand for telepsychiatry services has outpaced the evidence-based supporting its efficacy, ongoing evaluation of services will help the provider establish best practices. A "lexicon of assessment and outcome measures for telepsychiatry" is available at the ATA website (120). Evaluation may include process variables, such as description of the population served, appointments kept or cancelled, hospitalization, collaboration in the community, types of services provided. Routine measurement of outcomes helps to demonstrate patients' progress and effectiveness of services—particularly important for telepsychiatrists involved

with Accountable Care Organizations. Assessment of clinical outcomes may include rating scales obtained from the patient and stakeholders, functional assessments, documentation of adverse events, and adherence to treatment plans. Providers should also consider evaluating caregivers' burden (29). Exploration of the virtual relationship between the patient and provider could help to understand salient mediating factors when delivering care remotely. Kramer et al. (121) have described a model to inform overall telepsychiatry research design and Slone et al. (58) describe additional guidance specific to pediatric research settings.

SUMMARY

The convergence of increasing clinical need, decreasing resources, and technologic advances have made telepsychiatry an attractive approach to deliver evidence-based treatment to youth and families who are not well served by traditional models of care. However, potential telepsychiatrists must keep abreast of technical, financial, and regulatory changes in this rapidly evolving field. Establishing an authentic patient–provider relationship, and a successful practice, requires providers to expand their repertoire of interpersonal relatedness and online presentation to optimize patients' experience. These efforts are increasingly rewarded. Barriers to telepsychiatry are falling as individual states enact parity with in person services, as CMS expands criteria for services, and as research demonstrates the feasibility, acceptability, and effectiveness of telepsychiatry services. Communities are increasingly requesting services. It's time to connect.

SECTION VII

INTERFACE AREAS OF CHILD AND ADOLESCENT PSYCHIATRY

7.1 PEDIATRICS

CHAPTER 7.1.1 ■ INTEGRATING BEHAVIORAL SERVICES INTO PEDIATRIC CARE SETTINGS: PRINCIPLES AND MODELS

DAVID J. SCHONFELD AND JOHN V. CAMPO

SCOPE OF THE PROBLEM

Primary care is the label applied to community-based medical settings that offer first-contact personal health care that is comprehensive and longitudinal (1). Most American children make at least one primary care medical visit annually (2), and parents look to pediatric primary care providers (PCPs) as resources for addressing psychosocial problems (3). One important strategy with potential to improve access to pediatric behavioral health services and overcome existing barriers to care is the integration of such services within general medical settings such as primary care. An important concept related to primary care is that of the medical home, which is a model of team-based primary care delivery led by a personal physician that delivers accessible, continuous, comprehensive, coordinated, culturally effective, and patient- and family-centered care (4). The medical home provides or arranges for all of the patient's health needs, including preventive services and chronic illness management. Professional organizations championing the medical home include the American College of Physicians, the American Academy of Family Physicians, and the American Academy of Pediatrics (AAP).

The public health relevance of pediatric mental health (MH) problems is increasingly being appreciated, and their relevance to the medical home should be clear. It is estimated that between 15% and more than 25% of pediatric patients have a MH problem or disorder (5,6). The prevalence of MH problems of concern to pediatricians would be even greater if the MH needs of the parents of pediatric patients (e.g., maternal depression) were considered within the purview of pediatric PCPs (7). Due to the high prevalence of MH concerns in children and adolescents and the frequency of their contact with PCPs, it stands to reason that pediatricians and other PCPs are important resources for identification and early management of common MH problems and disorders.

MH disorders are among the most disabling of pediatric conditions, and are associated with interpersonal difficulties, poor school performance, and school absenteeism, with one-third of all school days missed by adolescents being MH related. It is therefore not surprising that psychosocial problems are the most common chronic conditions presenting during pediatric ambulatory health visits, with a broad range of severity and high rates of comorbidity, comparable to chronic conditions such as asthma and diabetes. Not only are MH disorders highly prevalent

across the lifespan, but early onset is more the rule than the exception, with pediatric psychiatric disorder being powerfully predictive of adult disorder and impairment. As demonstrated by the National Comorbidity Study, the onset of approximately half of all MH disorders occurs at or before age 14, with approximately three of four MH disorders beginning by age 24 years (8).

DUALISM IN PEDIATRIC HEALTH CARE

Despite a growing awareness of the biopsychosocial model of health and an appreciation that physical health and MH are inextricably linked, our health care delivery system is split into parallel systems of care depending on whether a problem is conceptualized as physical (general medical conditions) or psychological (MH disorders). While it is true that most professionals, when pressed, will agree that health is a unitary construct that cannot be parsed into physical and mental components, our behavior, the organization of health care, the systems of health care reimbursement, and the behaviors of our patients suggest otherwise. Whether a disorder is conceptualized as physical or mental thus has profound implications for how and where the disorder is cared for, which professionals are expected to bear primary responsibility for care delivery, and how that care is reimbursed. Due to the persistent stigma associated with MH disorders, there are additional societal implications resulting from whether a disorder is considered to be a general medical condition or a MH disorder. In contrast to physical disease, MH disorders are often viewed by our society as being under the voluntary control of the affected individual, the consequence of individual weakness, inadequacy, or moral failing, and thus associated with stigma, shame, and embarrassment.

Physical symptoms are a common presentation of psychiatric disorder in general medical settings, with disorders conceptualized as mental (e.g., anxiety and depressive disorders) commonly presenting to PCPs and medical specialists with very real and disabling physical complaints and distress (e.g., functional abdominal pain and headaches) (9–11). Such patients tend to utilize more health services which can be quite costly to society (12). Potentially serious physical health consequences have also been associated with pediatric MH disorders, most notably increased risks of suicide, violence, and accidental injury, as well as overweight, early pregnancy and alcohol, drug, and tobacco abuse (13–16).

Increasing attention over the past several years to the impact of early childhood adversity on children's emotional and physical health (including serious physical health conditions presenting in adulthood) has underscored not only the growing recognition of the interplay between MH and physical health, but the major public health impact of failure to prevent or mitigate these negative influences (17). Clinical guidance documents from the AAP instructing pediatricians on how to provide psychosocial support to children impacted by disasters and other crises (18) and how

to support grieving children and families (19) are recent examples of pediatricians' recognition of not only the need to identify and treat mental illness, but also the necessity to make concerted efforts to promote adjustment and coping for children facing adversity.

It is also well known that physical disease is a significant risk factor for the development of emotional and behavioral problems, with several studies documenting that chronic physical disorder is a risk factor for MH problems and disorders in both community-based and clinical samples across the lifespan (20–23). In part due to the success of modern medicine, chronic physical illness is a growing problem; approximately 1% to 3% of all youth suffer from significant functional impairment resulting from chronic physical illness (21). Physical diseases or injuries that affect the brain (e.g., epilepsy, cerebral palsy, head trauma) are especially potent risk factors for comorbid emotional, behavioral, and learning problems (23,24). The presence of a MH disorder can also influence the course of physical disease, as demonstrated in juvenile diabetes, where comorbid depression has been identified as an independent risk factor for the development of diabetic retinopathy (25), repeat hospitalization (26), overall adaptation to the disease (e.g., adherence to treatment), and possibly metabolic control (27). From this, it should be evident that disorders considered to be mental can have profound physical health consequences and vice versa.

IMPLEMENTING BEST PRACTICES WITHIN PRIMARY CARE SETTINGS

Research has demonstrated the efficacy of a growing number of treatments for common pediatric MH disorders (28), but most affected youth do not receive any treatment (4,29). Of those who do receive services, many are not treated in accordance with available best practices, with considerable gaps existing between research-driven knowledge and routine clinical practices (30,31). Interventions that have been proven efficacious for attention-deficit/hyperactivity disorder (ADHD) (30), anxiety disorders (32–34), and depressive disorders are generally not systematically or effectively applied on the population level, with routine care often falling short of best practices (35). Finding the means to translate advances in treatment efficacy into practical effectiveness strategies will thus be necessary to maximize public health benefits of new advances in therapeutics, and will likely require commitment, multidisciplinary collaboration, and systemic changes in the way that professionals in primary care and specialty MH care work together (36–38). Two examples of such an initiative to improve the quality of care for pediatric MH disorders in pediatric primary care settings are the effort by the AAP to develop practice guidelines for the diagnosis and management of ADHD (39,40) and another initiative involving the AAP in partnership with MH professionals to

develop guidelines for PCPs on the diagnosis and management of adolescent depression (41,42).

THE EMERGENCE OF DEVELOPMENTAL-BEHAVIORAL PEDIATRICS

The high prevalence of psychosocial problems in children within pediatric primary care settings was described by Haggerty in 1975 and termed the new morbidity. Due in part to the successes in preventive medicine (e.g., immunizations) and medical therapeutics (e.g., antibiotics), the nature of the pediatric needs of children and their families has changed, resulting in a growing emphasis on developmental and behavioral issues in pediatric care. Much of this alteration in practice pattern was also the result of a changing environment. Major changes in family, school, and neighborhood contexts over the past several decades resulted in an exacerbation and increase in developmental and behavioral problems along with a dramatic decrease in formal and informal social networks that might have in the past provided advice and guidance on their management.

The field of developmental-behavioral pediatrics (DBP) arose from the need to enhance the capacity of pediatricians to identify, manage, and when necessary, refer children with developmental and behavioral concerns and to implement effective prevention approaches. The goal was not to create a cadre of independent clinical subspecialists which might compete with child and adolescent psychiatrists, but to produce academic leaders and researchers that can enhance the training of general pediatricians so that they will be better prepared to address the developmental and behavioral needs of their own patients (43).

DBP focuses on the evaluation and management of common behavioral problems such as temper tantrums or sleep problems and attention-deficit disorders, common developmental disabilities such as autism spectrum disorders or intellectual disabilities, and physical complaints best addressed via a biobehavioral approach, such as recurrent abdominal pain. DBP aims to be eclectic and committed to multidisciplinary collaboration, with developmental-behavioral pediatricians striving to integrate a wide range of complementary theories derived from the medical, biologic, behavioral, and social sciences, and drawing upon clinical skills and research approaches that are otherwise associated with a range of disparate disciplines. As a result, there is significant overlap between conditions appropriate for management by developmental-behavioral pediatricians and other professionals, such as child and adolescent psychiatrists, neurodevelopmental specialists, pediatric neurologists, and child psychologists.

As the field of DBP matured, it became desirable to have a recognized subspecialty so that there could be a core faculty within academic medical programs to organize the teaching of medical students, residents, fellows, and other allied

health professionals, to conduct relevant research, and to assist in the delivery of clinical care. The Society for Developmental and Behavioral Pediatrics (initially called the Society for Behavioral Pediatrics) was formed in 1982; it is an international, interdisciplinary organization with over 900 members whose goal is to improve the health of infants, children, and adolescents by promoting research, teaching, and clinical practice in DBP (www.sdbp.org). SDBP has a well-regarded professional journal, *Journal of Developmental and Behavioral Pediatrics* (www.jdbp.org), which is devoted entirely to the developmental and psychosocial aspects of pediatric health care and written for physicians, psychologists, and other clinicians and researchers.

In 1999, the field of DBP was approved as a subspecialty by the American Board of Medical Subspecialties and the first subboard of DBP within the American Board of Pediatrics was established to work with the Residency Review Committee to develop guidelines for subspecialty fellowship training and to develop an examination for certification of subspecialists in DBP. The first application for accreditation of Fellowship Programs in DBP was accepted by the Accreditation Council for Graduate Medical Education in October 2002. Accredited fellowship programs in DBP accept trainees upon completion of an accredited pediatric residency program and are 3 years in duration. The fellowships comprise experiences in patient care to lead to the development of clinical proficiency, involvement in community or community-based activities, and development of skills in teaching, program development, research, and child advocacy. The first board certification examination in DBP was administered in November 2002, with the first certified subspecialists in the field in March 2003.

Both DBP and child and adolescent psychiatry are relatively young fields that share many commonalities. While DBP is firmly identified with traditional medicine by virtue of its subspecialty relationship to pediatrics, and child and adolescent psychiatry typically is considered to fall under the rubric of "mental health," DBP is increasingly integrating the insights offered by modern psychiatry and child and adolescent psychiatry is increasingly acknowledging its medical roots and connections to both pediatrics and psychiatry. The popularity of "triple board" training in pediatrics, psychiatry, and child and adolescent psychiatry, an alternative training pathway that also reflects a growing appreciation of the need to bridge the apparent gap between pediatric physical and MH care, also validates the importance of active collaboration among the disciplines.

SHARING THE CHALLENGE

Although collaboration between pediatrics and psychiatry has been a topic of considerable interest and discussion for at least half a century, the hope of integrating MH services into pediatric general medical settings has yet to be realized. Parallel

systems of care for physical and MH problems persist despite governmental recommendations to better integrate existing research-based knowledge into routine clinical practice (37), and existing models of reimbursement (e.g., behavioral health carve-outs) impair rather than facilitate meaningful collaboration. The scope and impact of pediatric emotional and behavioral problems nevertheless dictate that a response limited to the specialty MH sector is unlikely to prove successful in the short or long term, and is particularly unsuited to prevention efforts. Success in addressing the public health challenge presented by pediatric MH disorders will likely depend on multidisciplinary collaboration between child and adolescent psychiatrists, developmental-behavioral pediatricians, general pediatricians, family physicians, and affiliated MH professionals such as nurses, psychologists, and social workers, as well as efforts that span existing parallel systems of physical and MH care and reimbursement.

The public health importance of the primary care setting in the identification and management of common pediatric MH disorders is well recognized (3,38,44). PCPs manage the vast majority of recognized psychosocial problems (4) and prescribe the majority of psychoactive medications to American children and adolescents (37,45). Psychosocial problems are increasingly becoming the major focus of primary pediatric care for school-age children, but surveys of pediatricians suggest that they are among the most time consuming and frustrating problems to deal with in routine practice. PCPs report inadequate training in the management of pediatric MH problems (5,46), and low rates of PCP recognition of youth with MH disorders are the rule rather than the exception (3,44,46). Standardized assessment tools and/or diagnostic criteria are not in common use by PCPs in most clinical settings (47,48).

While pediatricians do identify many MH concerns in their patients (in most cases, identifying far more children in need of treatment than are able to access child MH care), most children with MH needs still go unnoticed. It has been estimated that roughly 20% of children and adolescents have MH problems that are severe enough to warrant treatment (that have a diagnosable mental, emotional, or behavioral disorder), but of this group, less than 20% to 30% receive appropriate MH services in the United States (49). In one study, pediatricians' overall sensitivity for the identification of emotional/behavioral problems among preschool children 2 to 5 years of age was only 21%, while specificity was 93% (50). As a result, just over half (52%) of the children who had an emotional/behavioral problem, based on an independent assessment by two psychologists who performed an evaluation of children who had a positive initial screen, did not receive any counseling, medication, or MH referral from the pediatrician. Pediatricians' assessments tend to have far higher specificity than sensitivity. While they may miss most children with emotional or behavioral problems, they tend not to over-diagnose. Recognition is better in children or adolescents with more severe disturbance and in those with stressful family situations. However, it is likely that early detection, when problems

are less severe and less recalcitrant to change, may respond better to less intensive interventions that could be provided in a primary care setting by the pediatrician.

Fortunately, studies have shown that the rate of identification of MH problems by pediatricians in the United States has increased dramatically over the past few decades. In one study, the rates of identification by pediatricians of any MH disorders, psychological symptoms, or social situations warranting clinical attention or intervention increased almost threefold between 1979 and 1996, from 7% to 19% of all pediatric visits among 4- to 15-year-olds (51). Identification, though, represents only the first step in addressing MH needs in children. Pediatricians require additional skills if they are being expected to assist with management of some MH problems. Studies have shown that even when such problems are identified by pediatricians, most are handled through watchful waiting and/or primary care counseling alone; the vast majority of children identified with a MH or psychosocial problem never obtain services from a traditional MH provider, but instead continue to receive services from their PCP (46). Available research suggests that only one in four children with newly recognized psychosocial problems is referred for specialty MH services, with less than half of those referred ever seeing a MH specialist (5). Professional expectations as to the scope of practice are also relevant. While pediatricians have increasingly focused on the evaluation and treatment of common behavioral problems such as ADHD, which is often a major focus of DBP practice, there is considerably more variability in comfort and practice with regard to other problems such as depression and anxiety. For example, while pediatricians feel an obligation to recognize pediatric depression, many do not consider depression treatment to be a core responsibility (52).

BARRIERS TO CARE

Barriers to MH care can be conceptualized as structural and attitudinal, and stigma likely is responsible for barriers of both types. Structural barriers can be fiscal, such as inability to pay and insurance restrictions. Relatedly, inefficiencies and deficiencies in the operational infrastructure of a health care system that segregates physical and MH care delivery services are important structural barriers to care, as are geography, transportation problems, shortages of competent health and behavioral health professionals, and a maldistribution of clinical services. Serious shortage of pediatric behavioral health specialists exists, and access to specialty behavioral health care is quite limited, particularly for low income, minority, and rural populations (5,46,53). Child and adolescent psychiatrists are particularly in short supply, which is unlikely to improve substantially any time soon given existing trends in training and support (54). Behavioral health specialists tend to cluster in more affluent and populous regions, which contributes to especially poor service access in rural areas and among low income and minority youth (55).

The primary care management of pediatric mental disorders often fails to meet recommended standards for treatment intensity and follow-up, with typically low rates of case recognition, evidence-based treatment, specialty MH referral, and referral completion (2,3,46). For example, PCP management of common disorders such as ADHD often fails to meet recommended standards for treatment intensity and follow-up (30), and PCPs are often uneasy caring for disorders other than ADHD such as depression (52,56,57). Effective care coordination for MH problems is lacking in most pediatric practices, and linkage after specialty MH referral is quite poor, with typically fewer than half of youth referred off-site to specialty behavioral health services receiving any services within the subsequent 6-month period (58–60).

Beyond structural barriers, attitudinal barriers to care such as lack of perceived need for treatment, mistrust of providers, a wish to manage problems within the family, and pessimism about the potential effectiveness of treatment can be quite significant (61). Such attitudinal barriers may be especially relevant for specific patient demographic, ethnic, and cultural groups, including with regard to prescription of psychoactive medications to youth (62), and may be every bit as relevant for providers as for patients and families.

Despite the high prevalence of MH and behavioral concerns in children and the reality that most identification and treatment of these conditions fall to pediatricians and other PCPs, up until fairly recently there was limited training for most pediatricians in this area. In 1978, the Task Force on Pediatric Education of the AAP identified child development and chronic disabling conditions as areas of graduate pediatric education that were in need of enhancement. About that time (and subsequently), surveys completed by primary care pediatricians confirmed that they felt they were not adequately prepared to handle developmental and behavioral problems.

The Residency Review Committee governing pediatric training responded to these concerns by requiring, in 1997, that all accredited pediatric residency programs include at least a 1-month block rotation, as well as additional integrated training experiences, in DBP which are directly supervised by faculty "with training in behavioral-developmental pediatrics." The vast majority of programs are now in compliance with this requirement, yet residency programs have found that providing quality training in DBP can be time-consuming and difficult. The assessment and management of behavioral concerns are highly dependent on the context; there is rarely a simple and direct approach that will work in all situations. Teaching pediatric trainees about the management of behavioral problems therefore requires opportunities for clinical practice under direct supervision and quality faculty who are able to model clinical management, precept the trainee's clinical care, and engage the trainee in a discussion of alternative management approaches, all of which take considerable faculty time and resources. Given the limited number of highly qualified DBP faculty in the country and the low reimbursement rate by health

insurers for their clinical services, this poses a significant challenge. In addition, many pediatric training programs provide only limited if any exposure to child and adolescent psychiatry.

Behavioral or MH problems in children may be associated with parent–child, family, or parental problems. Assessment and treatment of the child, the identified patient, often requires assessment and intervention with the parents, yet unlike child and adolescent psychiatrists, pediatricians have very limited training or exposure to the care of adults, particularly adults with serious MH disorders. Despite these barriers, there appears to be a growing recognition among practicing pediatricians of the importance and value of continuing education in DBP and MH topics, which currently are highly prevalent among continuing medical education offerings geared to the practicing pediatrician.

Just as pediatricians may have insufficient training in the diagnosis and treatment of pediatric MH problems, child and adolescent psychiatrists typically have insufficient training on how to establish effective consultative or collaborative relationships with pediatricians and in DBP issues. Child and adolescent psychiatrists often have not been exposed to, or lack sufficient experience with, anticipatory guidance and supportive management of common pediatric concerns and problems (e.g., management of common sleep problems and feeding difficulties), and neurodevelopmental issues have been relatively deemphasized as part of child and adolescent psychiatric training in many venues, at least until more recently. Likewise, developmental-behavioral pediatricians have focused considerably more than psychiatrists on neurodevelopmental issues and on the management of common pediatric problems, but have traditionally been less interested in the assessment and management of youth with serious psychopathology (e.g., bipolar disorder). Differences in training and experience likely have influenced relatively different orientations toward emotional and behavioral problems for child and adolescent psychiatrists and pediatricians, with the former tending to focus on the identification and treatment of MH disorders and the latter more oriented toward promoting overall child developmental health and wellness. One concrete illustration of these perceived differences in orientation was the development of the Diagnostic and Statistical Manual for Primary Care (DSM-PC) (63), which aims to help pediatricians identify and address the full spectrum of psychosocial situations or symptoms, ranging from developmental variations to problems to full disorders, that would benefit from intervention, even if the child's symptoms are not severe enough to meet the criteria for a specific MH disorder within the DSM used by child and adolescent psychiatrists. Furthermore, guild-related issues in these relatively young fields of child and adolescent psychiatry and DBP may not have provided sufficient time for the development of successful collaboration across respective clinical, educational, and research missions.

The traditional isolation and private office orientation of child and adolescent

psychiatrists and other MH professionals may also have served to limit and restrict meaningful collaboration with pediatricians. Different expectations about standards of confidentiality in MH and general medical settings can also serve to constrain artificially the sharing of information between PCPs and MH specialists. Current health care practices also undermine efforts to promote collaboration between pediatricians and child and adolescent psychiatrists. Increasing use of behavioral health carve-outs may diminish the willingness and ability of MH providers to establish creative collaborative care models with PCPs. Developmental-behavioral pediatricians who are qualified and interested in providing counseling services may find themselves excluded from behavioral health panels and/or forced to choose between reimbursement for either physical health or MH services, despite being qualified to deliver both and understanding the importance of delivering comprehensive care that integrates both components. Managed behavioral health care organizations usually restrict their focus to specialty MH and substance abuse services and fail to address MH services that are provided in primary care or general pediatric settings. Innovative practices and prevention models that depend on screening, evaluation, and early treatment in primary care for MH needs may not be recognized or reimbursed by either the general managed care company or the managed behavioral health care organization, and obtaining reimbursement for MH services provided in a general medical setting may often seem akin to trying to fit a square peg in a round hole. The escalating productivity demands placed on pediatricians and other PCPs requiring increased throughput of patients, coupled with the historically inadequate reimbursement for MH services provided by pediatricians (and indeed most cognitive services), place enormous time pressure on pediatricians who attempt to deliver such services within their practice setting or to engage in substantive collaborative care with child and adolescent psychiatrists or other MH professionals.

PRIMARY CARE: A BRIDGE TO COLLABORATION

Despite the challenges outlined earlier, the advantages of targeting quality improvement efforts in the primary care setting to address MH needs are quite clear and include familiarity, proximity, and relative acceptability for youth with MH disorders and their families. PCPs remain an important resource for families to address pediatric psychosocial problems, and can deliver services in the context of an established relationship (3). There are many reasons why families might wish to rely on their pediatrician to assess and manage many behavioral and MH problems. Pediatricians are one of the most trusted sources of health information and services and have established relationships with children and their families that often start at the time of the birth of the child, or may even begin during a prenatal visit. The frequent well-child checkups and sick visits, especially during the first few years of

life, help to develop the relationship further; the frequent contact promotes both accessibility and convenience. For pediatricians who adopt a biopsychosocial orientation, it is especially clear that it is counterproductive, and indeed impossible, to try to separate the physical and MH care components of pediatric services. Coupled with the limited accessibility to MH providers in many communities and the stigma associated with mental illness, it is understandable why most MH and behavioral concerns present first to the child's pediatrician. A focus on primary care also acknowledges the reality that primary care is the de facto MH care system for most youths with recognized MH disorders (5) and that PCPs prescribe the vast majority of psychoactive medications to youth (37,45). Delivering MH services in primary care powerfully communicates that physical health and MH are inseparable, and may aid in efforts to overcome stigma, improve communication between and among patients, families, and providers, and establish the foundation for meaningful educational and preventive interventions (46). Surveys of patients and families suggest that there is a preference to be seen in primary care for such problems rather than specialty care (1).

While it is recognized that high quality services for emotional and behavioral difficulties in primary care are generally multidisciplinary and collaborative (64), the evidence base necessary to make informed decisions about how to proceed in pediatric primary care is lacking. MH disorders such as ADHD, anxiety, and depression are most often chronic conditions that present with a broad range of severity, are commonly comorbid with other physical and MH disorders, and can exert their impact across the lifespan with a wide range of individual and family implications. Possible quality improvement strategies to address chronic MH problems in primary care settings include expanding the role of PCPs in managing common MH disorders, as well as the use of MH specialists as consultants to support the directed efforts of PCPs and/or to directly provide MH services within primary care (65). Adult depressive and anxiety disorders have been successfully managed in primary care using strategies that employ MH professionals as educators, consultants, supervisors, and/or direct service providers (66–68). Specialist participation in primary care beyond that of traditional off-site referrals can improve communication between PCPs and specialists, improve rates of referral completion, and enhance provider satisfaction (69). The collaborative office rounds model has been one attempt to support small case-oriented discussion groups that focus on MH needs of children presenting to primary care settings; these groups are jointly led by pediatricians and child and adolescent psychiatrists (70). Available research nevertheless suggests that specialist involvement alone is less potent in improving care than are systemic changes in care system design (71–73). A number of studies have used behavioral health specialists colocated in primary care to deliver standardized interventions for emotional disorders such as brief cognitive-behavioral therapy (74,75), interpersonal psychotherapy (76), and internet-based psychotherapy

(77). Applications specific to ADHD (78) and pediatric disruptive behavioral problems have also been applied in primary care, including the Incredible Years (79), Parent–Child Interaction Training (PCIT) (80), and the Triple P-Positive Parenting Program (81).

The *chronic care model (CCM)* provides a framework to address the complexities associated with integrating MH services into general medical settings, and shifts the focus of care toward a longitudinal rather than an acute or cross-sectional perspective. Goals include ensuring that a mutually understood and agreed-upon care plan is in place, that patients and families have the skills and confidence necessary to manage the condition, that the most appropriate treatments are available for optimal illness control and the prevention of complications, and that accessible and continuous follow-up care is available (72,82). There are six core elements of the CCM: (1) a *leadership* team composed of organizational partners, with leadership including specialists, generalists, and administrators with accountability for implementing the model; (2) *decision support* for direct care providers in general medical settings, which may include access to MH specialists and evidence-based guidelines to aid in the recognition and management of common MH disorders; (3) improvements in *delivery system design* to promote access to management guidelines and protocols. The use of a *care manager* responsible for coordinating care with PCPs and specialists has been promoted as an especially important element of delivery system design. The goal of a care manager is not to provide a nonphysician substitute for the PCP, but to complement and supplement the PCP's role by delivering services that the PCP does not have the skills or the time necessary to provide, such as formal psychiatric assessment, psychoeducation, and triage (72,73), as well as to facilitate communication among families, PCPs, and supporting specialists (66,73,82). Ideally, the care manager mediates specialty input to the primary care setting (66,71). The use of *patient care registries* to identify, manage, and track affected children can also modify the delivery system; (4) the use of *clinical information systems* to provide the technologic underpinnings necessary to facilitate the roles of PCPs, care managers, and MH specialists; (5) *self-management support* for patients and families that includes materials and processes that promote understanding of common MH disorders and treatment options in order to facilitate patient activation and shared decision-making; and (6) access to *community resources* independent of health care providers to aid patients and families (73,82).

A core value of the CCM is that optimal care is achieved when informed and motivated patients and families interact with a well-prepared and proactive care team that is comprised of a multidisciplinary and diverse group of clinicians who communicate and participate regularly in the care of a defined group of patients (73,82). As an adjunct, a "stepped care" approach emphasizes different levels of care depending on the type of specific disorder, its severity, complexity, and/or

persistence in the face of intervention, and acknowledges the need for specialty MH care for selected or treatment refractory patients and families (66,71). For example, a low severity disorder may initially be addressed through discussion of the disorder, basic psychoeducation for the patient and family, and watchful waiting, with higher levels of care being reserved for individuals suffering with the disorder at greater levels of severity and/or complexity. These higher levels of care might include initial management of the disorder in primary care by the PCP, followed by collaborative management in the primary care setting with the assistance of a care manager with specialty MH training, followed by referral for off-site specialty care. The CCM and stepped care approaches acknowledge that high quality illness management is multidisciplinary and collaborative, and a range of services and service delivery settings are indicated based on patient and family needs, since not all MH issues can be practically managed in the primary care setting (71–73,83).

INTEGRATED MENTAL HEALTH SERVICES IN PEDIATRIC PRACTICE

Adult experience with collaborative care approaches to the management of mental problems and disorders in primary care inspired initiatives in pediatric settings, and pediatric experience with this approach is growing (84). Collaborative care interventions have been applied in primary care to disruptive behavioral problems and disorders in children (58–60) and to depression in adolescents (35,84–87). A study of 321 children aged 5 to 12 years with disruptive behavioral problems and disorders used a cluster-randomized design involving 8 primary care pediatric practices to compare a collaborative care intervention known as doctor-office collaborative care (DOCC) to enhanced usual care consisting of psychoeducation and facilitated referral. The study found that the collaborative care intervention (DOCC) was associated with significantly higher levels of treatment initiation and completion, treatment response, consumer satisfaction, and PCP confidence relative to enhanced usual care (60). In the Reaching Out to Adolescents in Distress (ROAD) study, master's level clinicians were deployed as depression care managers and facilitated treatment for adolescent depression in primary care with antidepressant medication, brief cognitive behavioral psychotherapy, or the combination (87). The care managers for the ROAD intervention met weekly with a consulting psychiatrist, psychologist, and pediatrician. Compared to an enhanced usual care condition, adolescents randomized to ROAD were significantly more likely to receive depression treatment consistent with accepted standards (86% vs. 26%), respond to treatment (68% vs. 39%), achieve remission (50% vs. 21%), and report higher levels of satisfaction with care. A recent review and meta-analysis found that collaborative care interventions delivered stronger effects on outcomes than other attempts to provide integrated care, with an effect size of $d = 0.63$ reflecting a 73%

probability that a randomly selected child or adolescent struggling with a mental disorder in primary care would experience better outcomes in response to collaborative care than another randomly selected youngster receiving usual care (88).

We have previously described the feasibility of a "real-world" program within a large rural primary care practice in western Pennsylvania that relies on the relationship between PCPs and an on-site collaborative MH care team consisting of an advanced practice nurse (APN) with specialty MH training, a psychiatric social worker, and a child and adolescent psychiatrist (89). In this model, the PCP is the physician of record with responsibilities that include initial case identification, presumptive diagnosis, and ensuring the overall continuity of patient care. The APN serves as the primary liaison between the PCPs and psychiatrist (who is most often off-site), and functions as a bridge between primary and specialty care. The APN works closely with the PCP to complete an initial assessment and to triage each patient with an identified problem, with the goal of determining whether the child might benefit from services, and if so, where and how such services are best delivered. Treatment options include: (1) collaborative management with the PCP in primary care (generally appropriate for relatively straightforward, uncomplicated patients or those on a stable treatment regimen); (2) on-site MH comanagement by the PCP in collaboration with the primary care–based specialty MH team (such an approach might be appropriate for patients who failed earlier treatment by the PCP or patients of intermediate complexity or severity); and (3) off-site specialty MH referral (for patients with more complicated and/or severe disorders and those with psychosocial circumstances likely to render management within the primary care setting unsuccessful).

The APN provides patient and family education, ongoing case management and coordination, school liaison (e.g., requests and obtains teacher reports of patient behavior and performance), and treatment support services (psychopharmacology safety and outcome monitoring; brief psychotherapeutic support and intervention, including parent management training, simple behavior programs, and training in self-management strategies). The psychiatric social worker delivers brief psychotherapy for selected patients and families on-site and the child and adolescent psychiatrist provides MH team leadership, supervision, education, psychiatric consultation for selected cases (diagnostic dilemmas, treatment failures), and will occasionally comanage with the PCP cases requiring input from an experienced psychopharmacologist. Approximately two-thirds of newly evaluated patients are triaged to routine services delivered by the PCP with APN support, 20% are managed on-site by the PCP and MH team, and the remainder is referred to off-site specialty MH services. This rural program has been well received by PCPs, patients, and families, and patient and family compliance with initial assessment and triage visits has been quite high (91%) (89). This collaborative approach allows for MH

services to be delivered and supported by blending both general medical and behavioral health funding streams, but other approaches may be even more feasible, such as those built around an APN capable of billing for the assessment and primary care–based management of youth with emotional and behavioral problems via medical funding streams. A stumbling block for collaborative care approaches implemented outside a research setting arises from the practical difficulties of deriving fiscal support for specialist involvement that is not face to face with patients and families.

In response to the need for greater collaboration between pediatric PCPs and child and adolescent psychiatrists, several models using MH specialists to provide brief, focused input to PCPs have evolved, with most relying on the use of the telephone for consultation. Several statewide initiatives have championed this approach, including the Massachusetts Child Psychiatry Access Project (90) and the state of Washington Partnership Access Line (91). In these programs, PCPs can access a child and adolescent psychiatrist for a patient-focused telephone consultation on a broad range of issues, including diagnosis, intervention options, the specifics of management and ongoing monitoring, and determination of the most appropriate level of care. Other approaches have included training PCPs to improve skills related to MH and enhance their willingness and capacity to care for behavioral health problems and disorders by virtue of didactic presentations, group consultation, peer consultation, and clinical practice guidelines for the management of specific disorders. Relatively large-scale efforts focused on PCP training and ongoing practice-based consultation include the REACH Institute (www.thereachinstitute.org) and Ohio Minds Matter (www.ohiomindsmatter.org), a state-sponsored program to aid PCPs in the assessment and management of pediatric mental health problems and disorders with the aim of improving the quality and safety of psychopharmacologic practice.

Unfortunately, novel efforts such as those described above may prove to be “nonstarters” in the real world unless innovations in systems of compensation for the delivery of behavioral health care services are permitted to parallel innovations in care delivery models. Nevertheless, while challenging from a fiscal perspective, collaborative models that flexibly incorporate pediatric MH specialists into primary care appear to be feasible and compatible with the workings of medical practice. Recent health care legislation is beginning to result in shifts in health care financing that encourages an orientation toward promoting the health of a population (rather than exclusively compensating for the treatment of individual illnesses), which in turn has begun to incentivize integrated approaches to behavioral and physical health in order to improve access to high quality behavioral health services, enhance patient outcomes, and decrease overall health care costs. A recent meta-analysis of randomized controlled trials evaluating the benefits of integrated care for children and adolescents has demonstrated positive behavioral health care outcomes when

compared to primary care alone, with the greatest effects seen in the area of treatment interventions that used collaborative care models and that targeted MH problems (88).

CONCLUSION

Health is a unitary construct that cannot be effectively parsed into physical health and MH, and thoughtful collaboration between child and adolescent psychiatrists, developmental-behavioral pediatricians, general pediatricians, and other professionals involved in pediatric care is critical to ensure the quality improvement efforts deserved by children everywhere. Integration can help address both structural and attitudinal barriers to behavioral health care delivery and challenge stigma. The familiarity, proximity, and acceptability of the primary care setting builds on established child and family relationships with PCPs. The PCP's attention to MH concerns communicates the powerful message that physical health and MH are inseparable. Equipping PCPs with the requisite knowledge and skills to identify, evaluate, and manage common developmental and behavioral concerns is a major goal of the field of DBP, and child and adolescent psychiatrists are increasingly contributing to such efforts. The integration of MH services into primary care may aid in efforts to overcome previously identified barriers to intervention, such as cost and transportation problems, stigma, and perceptions that treatment is not relevant, and strained relationships with MH service providers (92). Stepped collaborative care approaches that bridge primary and specialty care, as well as traditional medical care and behavioral health care, have the potential to facilitate patient and family access to MH services, improve adherence with initial MH contacts, decrease time between initial MH referral and active treatment, increase the quality of MH services in primary care, reduce stigma, efficiently integrate specialty MH professionals into primary care medical practice, and challenge false dichotomies between physical and MH care and reimbursement strategies. Collaborative care interventions for pediatric mental health problems and disorders have been demonstrated to be feasible and to improve access to behavioral health services, outcomes, and patient and family satisfaction relative to existing care models. Beyond modifying fiscal and regulatory models to accommodate the application of collaborative care interventions in pediatric general medical settings, changes in patient, family, and provider attitudes are likely necessary as well. Research on the successful dissemination of evidence-based collaborative care interventions is needed.

CHAPTER 7.1.2 ■ PEDIATRIC CONSULTATION LIAISON

LAURIE CARDONA

During the last two decades, there have been dramatic improvements in the treatment of previously life-threatening childhood diseases. The improvements have included: the development of newer vaccines and greater dissemination of immunization programs, improvements in surgical techniques for congenital conditions, advancements in the care of premature infants, broader implementation of prenatal and newborn screening for genetic conditions, and the development of standardized models of medical care, as in the treatment of childhood cancers (1). These medical advances have resulted in significant declines in the incidence and overall impact of childhood diseases. For example, today, the 5-year survival rate for pediatric leukemia is 95%, and there are similar trends with all the major childhood illnesses. Nevertheless, it is estimated that approximately 8% of children have a chronic health condition that affects their daily functioning. Furthermore, data show that children living in poverty are particularly at risk for the development of a chronic health condition (1). Thus, the need for timely mental health assessments and interventions with this population of children becomes of even greater importance.

Children with medical disorders appear to be at increased risk for the development of mental health difficulties in comparison to healthy peers. A 2011 meta-analysis, which integrated the findings from 569 studies, revealed that children and adolescents with a chronic physical condition have higher levels of internalizing problems (somatic complaints, anxiety, depression, social withdrawal) and externalizing problems (aggressive behaviors, delinquent behaviors) in comparison to healthy peers or the test norms (2). There were notable differences across various disease types; for example, there were large elevations in internalizing problems for children with chronic fatigue syndrome and moderate elevations in children with migraine headache, epilepsy, chronic kidney/liver disease, asthma, inflammatory bowel disease, and spina bifida. Moderator effects such as socio-demographic characteristics were also evident. Accordingly, there were stronger elevations of problems in children with chronic illnesses living in developing countries. Gender differences were also evident in the analyses, such that boys exhibited higher rates of externalizing problems.

Families and primary caregivers can also be deeply affected by a child's medical condition. The challenges can vary according to disease, however studies have identified a variety of stressors that confront families including: significant changes in daily routines, increased financial burdens, reduced or loss of employment, social isolation, and marital strain (3). Furthermore, parents of chronically ill children have reported significantly lower health-related quality of life (4); and there is evidence

that some parents may develop formal psychiatric symptoms. Parents of childhood survivors of cancer, for example, report posttraumatic stress symptoms associated with the distress of their child's cancer treatments (5). Given the significant burdens of caring for a chronically ill child, the family's level of functioning, coping, and adaptation can become compromised, which will in turn influence child adaptation.

BIOPSYCHOSOCIAL MODEL OF CHILD ADAPTATION TO ILLNESS

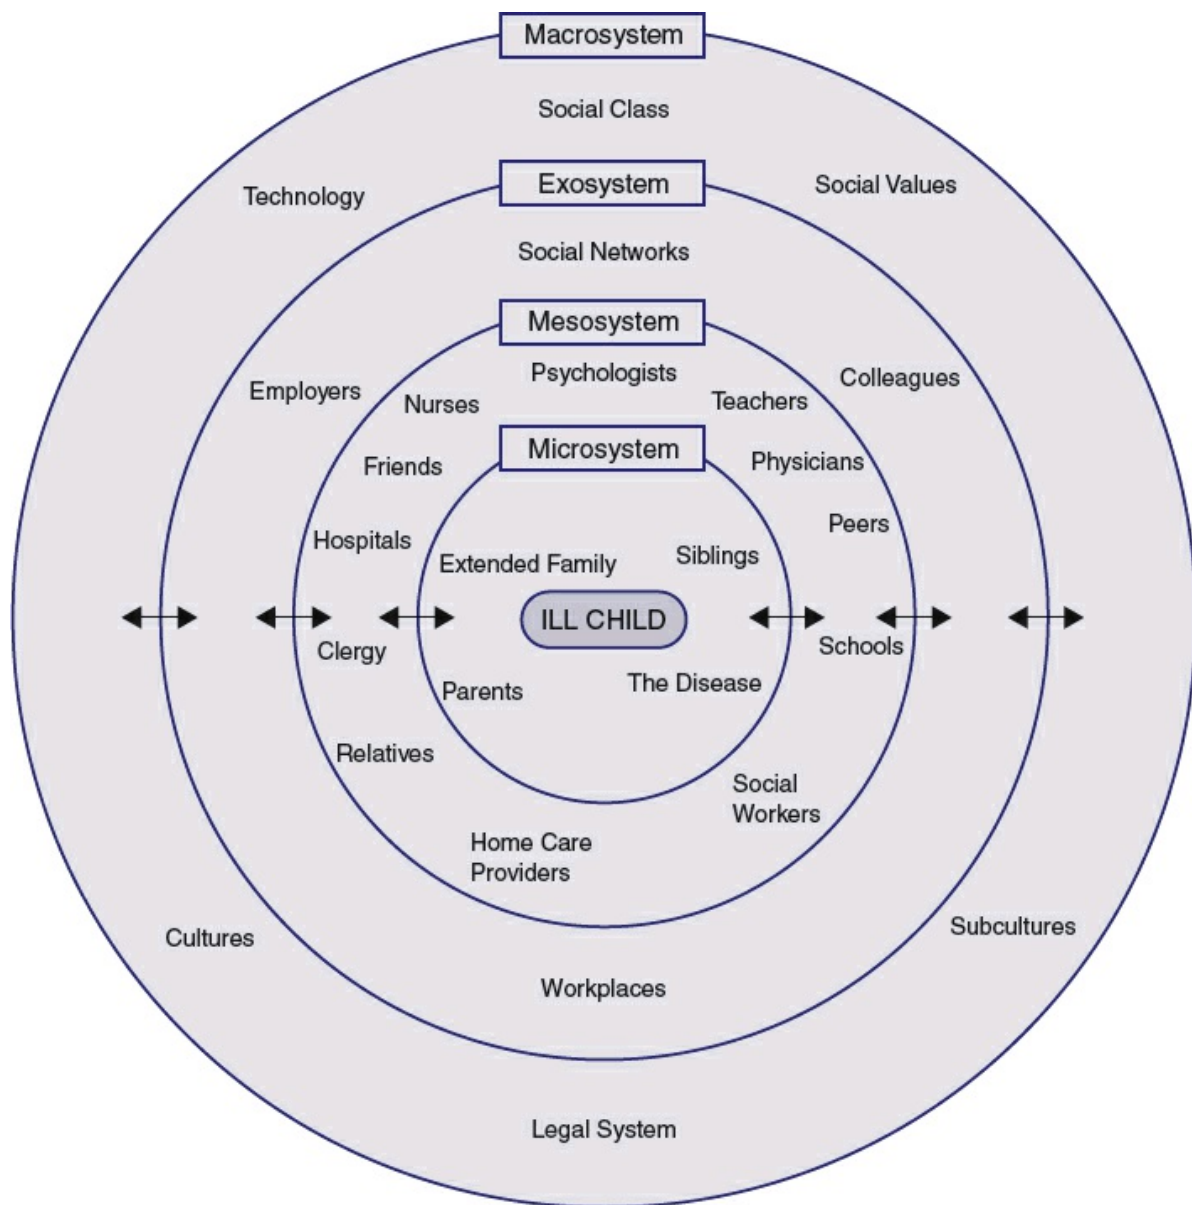
Historically, pediatric consultation work has largely focused on assessment and intervention with the child and family. Research has documented, however, that there is a complex interplay between child-centered variables, family context, treatment providers and broader systems which can all impact a child's psychological adjustment. Furthermore, there is growing recognition that a child's medical illness also impacts siblings, extended family members, peers, and even community members. Therefore, a biopsychosocial approach to the assessment of a child and family's psychological adjustment provides the most comprehensive framework. Kazak's adaptation (6) of the Brofenbrenner social-ecologic model of child development provides a cohesive overview of the multiple influences on child and adolescent adaptation to medical illness (Figure 7.1.2.1).


FIGURE 7.1.2.1. A social-ecologic model of children with pediatric illness. (Reprinted from Kazak AE, Segal-Andrews AM, Johnson K: Pediatric psychology research and practice: A family/systems approach. In: Roberts MC (ed): *Handbook of Pediatric Psychology*. 2nd ed. Guilford Press, 1995, p. 88, with permission.)

Kazak's framework features basic theoretical tenets of (a) multiple layers of influence (nested systems) and (b) bidirectionality of influence on psychological functioning and adjustment. Factors influencing a child's functioning and adaptation are nested within systems that extend from intraindividual (e.g., cognitive functioning) to larger ecologic influences (e.g., medical technology).

As illustrated in Figure 7.1.2.1, systems of influence are nested within one another and represent diminishing causal influences on the patient's adaptation and functioning. The innermost circle is symbolic of the child with pediatric illness and the intraindividual factors that impact the child's psychological adjustment and functioning. Examples of intraindividual variables include a child's level of

cognitive functioning, developmental level, temperament, and capacities for coping. These individualistic characteristics can be affected significantly by an array of disease-related variables. Accordingly, disease-related influences that can impact a child's functioning include: restrictions in physical mobility, chronicity of pain, and central nervous system involvement, as in the case of the untoward "late effects" of cranial radiation (7).

The microsystem also involves the patient's most immediate social relationships, including parents, siblings, and extended families. As with healthy children, the role of parental psychological functioning is a significant contributor to child adaptation, particularly to medical illness. Microsystem influences are deemed the most proximal and salient causal influences on the child's adjustment. Mesosystem influences consist of more distal social and ecologic influences on the patient's adaptation, exemplified by peers, school personnel, and an array of medical and mental health providers within the hospital setting and beyond.

Exosystem influences consist of a variety of contexts that impact social relationships and functioning within the mesosystem. Finally, macrosystem influences are those that impact the entire system, such as cultural beliefs, social values, and, particularly relevant to pediatrics, medical technology. These larger systems may have an equally profound impact on the family and child, as in the case of access to health insurance and to specialized medical care, which have become increasingly daunting challenges for many families.

RANGE OF C/L SETTINGS AND ACTIVITIES

Pediatric psychologists and psychiatrists conduct an array of patient-based clinical services. Additionally, they become involved in activities such as development of programs for promotion of health and prevention of health and psychological problems; education programs for pediatricians and family physicians regarding general child development issues; advocacy regarding child health and mental health at the public policy level; and applied clinical research (8).

Roberts (8) described five settings in which pediatric psychology services are most commonly provided: (1) inpatient medical center units, including C/L services for neonatal units, oncology units, respiratory care units, and ICU; (2) outpatient medical clinics such as primary care centers, pediatric oncology clinics, genetics clinics; (3) outpatient clinics providing care for children with psychiatric disorders; (4) specialty facilities such as rehabilitation centers and hospice; and (5) camps or groups such as summer camps for children with diabetes, and support groups for children and their parents.

The American Academy of Child and Adolescent Psychiatry (AACAP) and the American Academy of Pediatrics proposed that mental health services should be increasingly integrated into primary care systems of care (9). While this is a move

away from traditional practice models of inpatient consultation or referrals to an outpatient mental health clinic, it is expected that integrated and co-located mental health care will likely increase in the future Act (10). The benefits of co-located care include: improving access to mental health, increased communication and collaboration between primary care providers and psychiatry, and it allows ready implementation of standardized screening measures and evidence-based psychosocial treatments (11). Within a model of co-located care, the mental health clinician can have varying degrees of interaction with the primary care physician, from seeing patients in separate offices within the same facility, to seeing patients together, coordinating case conferences and clinical team meetings, and conducting case-based teaching for primary care staff (11).

The empirical efficacy of collaborative care models was examined through a 2015 meta-analysis of randomized clinical trials that evaluated whether integrated medical-behavioral health care for children and adolescents leads to improved behavioral health outcomes (12). The meta-analysis included 31 studies and found a significant benefit to integrated care, relative to usual care on mental health outcomes. Specifically, the probability was 73% that a randomly selected youth would have a better outcome after receiving collaborative care, than youth receiving usual medical care. The study also concluded that collaborative care had the strongest effect in those treatment trials that included evidence-based medication algorithms plus evidence-based psychotherapy.

Another promising and emerging method of collaborative care has been Telemedicine, in which the use of interactive video technology, web-based support, as well as phone calls, allows patients, pediatricians and mental health providers to work together over large geographic areas. Two such programs, one established in Massachusetts in 2005 (Massachusetts Child Psychiatry Access Project) and the other in Washington State in 2007 (Washington State Partnership Access Line) provide pediatric primary care practices with access to mental health consultation through phone hot-lines. A review of the Massachusetts Program (13) indicated that primary care physicians used the service most often for diagnostic questions (34%), identifying community providers (27%), and questions about medications (27%). A review of the Washington State program (14) revealed that 66% of the calls were regarding pharmacologic questions and 87% of the calls resulted in new psychosocial treatment advice.

As pediatric psychologists and psychiatrists become increasingly accessible to patients and families through systems of collaborative care, the challenge is for practitioners to become even more flexible and facile in providing a broad range of assessment and intervention services. In order to do so, they must develop knowledge and practice competencies across a broad range of domains. Content knowledge in the areas of typical child development, child psychopathology, psychological and psychiatric treatment modalities, and consultation with multiple professional

disciplines has been identified as prerequisite to effective C/L work (15).

TYPES OF REFERRAL QUESTIONS

Psychiatric assessment of child and family adjustment is a core service provided by mental health consultants. Within inpatient pediatric settings, the most frequent reasons for psychiatric consultation are problems with coping/adjustment, noncompliance with treatment, depression, suicide attempt, pain management, psychosomatic problems, and anxiety (16,17). Medical teams may also request assistance with managing patient behavior on the hospital ward (disruptive behavior, procedural distress), parent coping, as well as assistance with postdischarge treatment planning (referral for mental health services, inpatient psychiatric hospitalization, school re-entry). Reasons for referral can also vary according to the expertise of the C/L consulting service. For example, if there are specialists with eating disorders on the C/L service, then there may be a preponderance of requests from the medical teams for evaluation of patients with eating disorders. Finally, psychiatric consultation may be a part of the standard practice for certain medical subspecialty groups in which all children with a chronic illness (e.g. cancer, sickle cell, diabetes) and their parents, receive ongoing psychosocial evaluations and treatment as part of the child's medical care. Indeed, in the recently published Standards for the Psychosocial Care of Children with Cancer and Their Families (18), there are 15 standards which are proposed, one of which is that children with cancer and their family members should "routinely receive systematic assessments of their psychosocial health care needs." Furthermore, it is also recommended that long-term survivors of childhood cancers also receive yearly psychosocial evaluations.

Assessment approaches can be problem focused in scope, or involve a comprehensive multisystem evaluation approach. Structured interview methods, including the formal mental status examination, as well as standardized behavioral and psychological instruments are typically included in assessment procedures.

EMPIRICALLY SUPPORTED PSYCHOLOGICAL ASSESSMENT AND INTERVENTIONS IN PEDIATRICS

Currently there is a broad range of evidence-based assessment measures that provide standardized methods of evaluating child and family coping along a variety of outcome domains. A Special Issue in the Journal of Pediatric Psychology in 2008 provided a comprehensive review of standardized measures applicable to pediatric mental health (19). These and subsequent measures that have been developed, are rated as "Well Established" if they meet the Chambless criteria endorsed by APA. A complete listing of Evidence Based Assessment Resources is updated annually

through the website of Division 54 of the Society of Pediatric Psychology and is available to clinicians as well as researchers (20).

A closer look at the listing of standardized assessment tools reveals that there are evidence-based assessment tools that evaluate numerous domains relevant to pediatric mental health, including: Measures of Family Functioning, Health-Related Quality of Life and Functional Impairment, Adherence to Medical Treatments, Pediatric Pain, Psychosocial Adjustment and Psychopathology, and Stress and Coping. There are also specialized assessment resources for specific pediatric populations, such as Chronic Pain and Functional Impairment; Craniofacial Populations; Obesity; and Pediatric Gastroenterology (20). Given the breath of available measures, evidence-based assessment approaches can thus be readily incorporated into a consulting clinician's routine practice.

Similarly, highly effective, evidence-based psychosocial treatments for chronically ill children can be readily adopted by C/L clinicians. A recent review of psychological interventions for mental health disorders in children with chronic physical illness (21) suggests that cognitive-behavioral treatments for depression, such as those that have been well validated in healthy children, can be of benefit to medically ill children. Interventions for depression typically include elements such as: mood monitoring, problem solving, and behavioral activation. Cognitive-behavioral treatments for anxiety, which include components of cognitive restructuring and exposure exercises, have also been demonstrated to reduce anxiety in pediatric populations. Other reviews have concluded that cognitive-behavioral therapy is a well established treatment for procedure-related pain. These typically include components such as breathing exercises, training in relaxation strategies, self-hypnosis, cognitive coping skills, mental imagery, behavioral reinforcement with rehearsal, and directed coaching by a parent or practitioner in which the child is prompted to engage in coping skills (22).

It is important to note as well, that many cognitive-behavioral treatment programs for medically ill children include a range of modifications such as psychoeducation about the relationship between physical illness and mood; family education sessions; use of simplistic/concrete language; sessions in the homes; and telephone appointments (21). In sum, these findings are quite promising, but much work is still needed to further our knowledge of the most effective treatments for children with medical and psychiatric problems.

FRAMEWORKS FOR CONSULTATION AND LIAISON

Numerous theoretical and practical frameworks have been described to capture the complex nature of the pediatric consultation process (23–26). These models all share the common features of providing guidelines to psychiatric consultants for fostering professional relationships with healthcare providers and patients in order to improve

patient care, and to promote the understanding of child and family adjustment to illness or hospitalization (27). The various models of consultation vary with regard to: degree of contact and direct involvement with the patient, degree of involvement with the medical team, the length of time that the consultant remains available to the medical team, and the degree of "shared caregiving" that is established.

Accordingly, the most time-limited model is Resource Consultation (23), also known as Independent Functions consultation (24). In these consultation approaches, the psychiatric consultant addresses a very specific diagnostic question and then offers a set of recommendations to the team and family regarding intervention strategies for the identified problem. Further follow-up and evaluation are generally not offered. In the second type of consultation approach, the Process Educative model (23), the psychiatric consultant offers indirect psychological support to patients by means of advising and educating the medical staff about psychological or pharmacologic treatment strategies. The consultant may not actually have contact with the patient, but instead consults with the pediatrician about their questions. A third consultative approach is the Collaborative Team model (24) in which the psychiatric consultant and the medical team have equal responsibility and decision making in the care of the patient, and is therefore one of "shared caregiving."

CONSULTATION PROCEDURAL GUIDELINES

In 2009, the AACAP published a practice parameter, entitled, "Practice Parameter for the Psychiatric Assessment and Management of Physically Ill Children and Adolescents" (7). This "clinician-oriented" parameter had the aim of delineating important components of assessment and management of physically ill children (Table 7.1.2.1).

TABLE 7.1.2.1

PRINCIPLES FROM THE AACAP PRACTICE PARAMETER FOR THE PSYCHIATRIC ASSESSMENT AND MANAGEMENT OF PHYSICALLY ILL CHILDREN AND ADOLESCENTS (2009)

1: Mental health clinicians should understand how to collaborate effectively with medical professionals to facilitate the health care of physically ill children.
2: The reason for and purpose of the mental health referral should be understood.
3: The assessment should integrate the impact of the child's physical illness into a developmentally informed biopsychosocial formulation.
4: General medical conditions and/or their treatments should be considered in the etiology of a child's psychological and behavioral symptoms.
5: Psychopharmacological management should consider a child's physical illness and its treatment.
6: Psychotherapeutic management should consider multiple treatment modalities.
7: The family context should be understood and addressed.
8: Adherence to the medical treatment regimen should be evaluated and optimized.
9: The use of complementary and alternative medicine should be explored.
10: Religious and cultural influences should be understood and considered.

11: Family contact with community-based agencies should be considered and facilitated where indicated.
12: Legal issues specific to physically ill children should be understood and considered.
13: The influence of the health care system on the care of a physically ill child should be considered.

Other C/L consultation protocols (28,29) have included specific procedural guidelines in the consultation process such as: (1) defining the referral questions; (2) review of records; (3) interview of primary caretakers; (4) assessment of the patient; (5) referral for additional tests or procedures; (6) assessment of interdisciplinary relationships between medical personnel; (7) collaboration with community agencies or schools; (8) diagnostic feedback and recommendations; (9) intervention phase; and (10) follow-up.

Referral Phase

Initially, the psychiatric consultant should speak directly to the primary physician, and other members of the medical team (primary nurse, residents, or pediatric social worker) to generate a list of concerns or diagnostic questions that are to be addressed during the consultation. It is critical for the consultant to listen for both implicit as well as the explicit messages from the medical team (29). For example, the team may actually have more concerns about parental coping than they do about child psychological adjustment. During the referral phase, it is also important that the consultant take a thorough medical history and current treatment regimen from the referring physician. Finally, it is important that the consultant confirm that the parents and patient have been informed by the medical team about their concerns and that they have agreed to participate with the evaluation (30).

Record Review

Prior to meeting the family and patient, it is important for the consultant to review the medical chart, including prior medical records, for treatment information that may have been omitted by the referring physician. For example, for those patients who have multiple medical subspecialties involved in their care, it is important to review the treatments or consultations provided under their care. Additionally, oftentimes nurses and child life specialists document important observations regarding a child's mental status, mood states, and behavioral functioning that are important sources of data. As part of the record review, it is also critical that the consultant take note of all the medications prescribed to the patient, with particular emphasis on those medications that have psychoactive effects or withdrawal symptoms.

Furthermore, it is useful to obtain additional records or conduct interviews with community-based services such as the child's school (to ascertain information about developmental, cognitive, and academic functioning), community mental health

providers and child welfare agencies, if they have been involved with the child and family (30).

Interview with Primary Caretakers

It is usually most informative to begin the evaluation phase with a structured interview with the primary caretakers, which may include biologic parents, foster or adoptive parents. Designated social service agency workers may also need to be contacted in the case of children who are in state custody. During this interview, the consultant should gather information regarding the patient's birth, developmental, social, and educational histories. Of particular importance is the child's history of past psychiatric treatments, history of educational or psychological assessments, and their adherence with ongoing medical care (30).

Additionally, the consultant should inquire about the parents' social and psychiatric histories, parenting styles with the ill child, the marital relationship, sibling relationships, extended family supports, economic and community resources available to the family. To complement a structured interview with primary caregivers, the mental health consultant can also include standardized assessment questionnaires such as The Family Environment Scale (31), the Impact on Family Scale (32), or Coping Health Inventory for Parents (33), along with numerous other measures available for review through the APA Div. 54 Evidence-based Assessment Resources (20).

The interview with the parents should also include a discussion of the family's cultural and religious beliefs regarding the nature of the child's illness, their acceptance of the medical diagnoses and their views about the proposed medical treatments. These views are likely to affect a child and family's acceptance to treatment, as well as help identify potential sources of support for the family and child (7). Thorough assessment of these various family domains is critical because difficulties within any of these areas have been identified as potential risk factors for children with serious medical conditions.

Child and Adolescent Assessment

A comprehensive mental status examination should be conducted with the child, as is permissible given the patient's age and developmental level of functioning. Areas of inquiry may include: the child's understanding of their illness, treatment, and prognosis; the impact of the illness on the child's relationships with their parents, siblings, and peers; the impact of the illness on their school performance; and the child's view of the medical team providers.

Play interviews and observations of the child's behavior during inpatient ward activities are also valuable sources of data. During the evaluation phase,

standardized diagnostic procedures such as self-report inventories for depression (e.g., Children's Depression Inventory) (34), anxiety (e.g., Screen for Child Anxiety-Related Emotional Disorders) (35), child health–related quality of life (e.g., Pediatric Oncology Quality of Life Scale) (36), and pediatric pain (e.g., Varni-Thompson Pediatric Pain Questionnaire) (37), may also be included. For those patients with altered states of consciousness, such as possible delirium, repeated serial interviews are necessary. Additionally, use of structured observations, such as nursing ratings with a measure such as the Cornell Assessment of Pediatric Delirium (38), are often critical in order to establish levels of baseline functioning and to explore possible etiologic factors.

Referral for Other Tests or Procedures

Over the course of the evaluation, a range of differential diagnostic questions may arise that will lead the consultant to request additional tests or procedures from the medical team. For example, the consultant may suggest neuroimaging studies or an EEG for a patient with acute changes in mental status. Additionally, neuropsychological testing is often indicated in the context of further clarifying functional capacities for children with central nervous system insults, as in the case of seizure disorders or brain tumors (30).

Systems Assessment

The final components during the assessment phase involve examining the relationships that exist among medical personnel, the child–family system, and relationships among medical personnel and community systems such as schools and social service agencies. The consultant may need to conduct systematic interviews and observations of all these various systems relationships in order to determine whether there are communication or collaboration difficulties contributing to the child's observed difficulties. Clinical researchers such as Kazak (39) suggest that a systems assessment is important because oftentimes family or family–staff interactional factors can play a central role in the child's problematic functioning.

Diagnostic Feedback Phase

Once the consultant has concluded all of the components of the assessment, the next step is to share the diagnostic formulation and set of recommendations with members of the medical team, parents, child, and other systems of care. Typically, consultation findings are summarized within the context of a report placed in the electronic medical chart. It is of paramount importance, however, that the consultant communicates orally with the medical team and family regarding the findings and the

recommendations for intervention. Direct discussion of the multiple factors that are contributing to the child's adjustment difficulties can then lead to candid discussions regarding the roles that each member of the medical team or family can assume in promoting improved child adaptation (30). It is important for oral and written communications to be provided in a timely manner, and in language that is concise and free of psychiatric jargon. A developmentally informed feedback discussion with the child and adolescent patient should also be conducted.

Finally, it is equally important for the mental health consultant to communicate the findings and recommendations of the evaluation process to the child's primary care pediatrician, as well as any additional medical specialists responsible for the child's care.

Interventions and Follow-up

Numerous evidence-based treatments have been developed to address child and family coping with acute and chronic illness. For example, there are highly effective cognitive-behavioral treatments such as progressive muscle relaxation and guided imagery training to address pain and anxiety during invasive medical procedures (22). Additionally, there are home-based, manualized, behavioral family therapy treatments targeting issues such as poor medical adherence and family conflict (6). Cognitive-behavioral methods are also useful in addressing more broad-based psychological problems such as anxiety and depression (21). Pharmacotherapy may also become an important component of a medically ill child's treatment regimen. For example, the psychiatric consultant may offer recommendations for medical management of symptoms related to behavioral agitation, delirium, depression, or anxiety. Referrals for occupational therapy, physical therapy, and neuropsychological testing may also be important components of a comprehensive treatment plan.

Additionally, a host of psychosocial interventions may be required. Accordingly, the family may require assistance in securing public assistance, special education services, support groups for children and family members, specialty summer camps, or supportive marital therapy. Some interventions may be possible to introduce within the context of a hospitalization, but oftentimes the psychiatric consultant must provide the family and medical team with suggestions regarding other community-based mental health professionals that can begin to develop a psychological plan of care. If the child will return to the school setting, an important part of consultation should include guidance regarding the child's reentry to school (30).

BARRIERS (AND PROPOSED SOLUTIONS) TO EFFECTIVE CONSULTATION AND LIAISON SERVICES TO PEDIATRICS

Several barriers to effective C/L service to pediatrics have been identified in the

literature, such as lack of timely availability of child psychiatry/psychology consultants, time constraints, and contrasts between illness-oriented and biopsychosocial conceptualizations (28). Perhaps the most significant barrier to effective C/L consultation to pediatrics is the difference in the pace of work between the two clinical traditions. The typical psychiatric consultation takes several hours and even days, while the work within pediatric hospital settings moves much more quickly.

Therefore, flexible consultation and treatment approaches have been identified as mechanisms to increase satisfaction and subsequent use of consultation services. Other matters of practical importance involve accessibility of the psychiatric consultant, responsiveness to the consultation request, and minimal time to complete the assessment and share the findings (40). Consultation services are also enhanced with effective communication of assessment findings, collaborative treatment planning, and practical recommendations to both the referring pediatrician and the child and family. For both family and professional audiences, communication should be practical, action-oriented, and free of psychological jargon; for the pediatrician, written communication should be concise.

Improved communication and collaboration can also be facilitated through the consultant's presence during clinical rounds, departmental meetings, and teaching conferences (28). Furthermore, a consultant can demonstrate leadership by offering to develop hospital-based or office-based psychological and behavioral management protocols such as: management plans for eating disorders and other self-harming behaviors, pain management protocols, and end-of-life protocols.

Finally, a consultant that also offers to provide the pediatric team with support and education about common childhood psychiatric conditions and their management, advice about working with challenging children and families, and is available to discuss the professional and personal challenges of caring for medically ill children can then become viewed as an integral member of the health care team.

7.2 MENTAL HEALTH ISSUES IN THE MEDICALLY ILL CHILD OR ADOLESCENT

CHAPTER 7.2.1 ■ CANCER

CASEY WALSH AND BRADLEY J. ZEBRACK

The American Cancer Society and the National Cancer Institute estimated that approximately 15,780 new cases of cancer in children and adolescents aged 0 to 19 years were diagnosed in 2014 (1). Approximately 1 in 285 young people in the United States will be diagnosed with cancer before the age of 20 (1). Although childhood cancer is rare, it is the leading cause of death from disease among children aged 1 to 14, resulting in an estimated 1,350 pediatric deaths in the United States in 2014 (1). Among adolescents (ages 15 to 19), there were an estimated 5,330 new cases of cancer diagnosed in 2014, as well as approximately 610 deaths from cancer (1).

Prior to the 1970s and the advent and use of multimodal chemotherapy, children diagnosed with cancer had little hope of long-term survival. However, advances in treatment, including the large-scale coordination of treatment through clinical trials, have greatly increased the long-term life chances of these young people. Notably, mortality rates for all pediatric and adolescent cancers combined have declined steadily from 1975 to 2010 by an average of 2.1% per year, resulting in an overall decline of more than 50% (1). Today, surviving childhood cancer is considered the norm rather than the exception.

Due to successes in treatment, much of the older literature on psychosocial outcomes for children with cancer is no longer relevant to current and future cohorts of patients, survivors, and their family members. Psychosocial studies of children with cancer and their parents were initiated in the 1970s (studies of off-treatment survivors began in the early 1980s with Koocher and O'Malley's (2) groundbreaking work entitled *The Damocles Syndrome*), and occurred at a time when childhood cancer survivors were considered miracle children.

Contemporary trends in the psychosocial literature on childhood cancer encompass some or all of the following elements: (1) a developmental approach in which the issues experienced by children of various ages are treated in the context of their normative physical and psychosocial maturation; (2) a family systems approach emphasizing interactive impacts and responses in families and among family members; (3) a stress-coping framework recently amended with a focus on posttraumatic effects; (4) advancements in web-based technology. The recently published "Standards for Psychosocial Care for Children with Cancer and Their Families" provide evidence-based clinical standards for the psychosocial care of children with cancer and their families from the time of diagnosis through survivorship or end-of-life and bereavement care (3). This incredible resource, developed by an integrated team of leading psychosocial clinicians and researchers, is being released as a special edition of the journal of Pediatric Blood and Cancer,

and has been funded by the Mattie Miracle Cancer Foundation (4). For people diagnosed with cancer it is useful to examine their experiences in the context of "survivorship"—the health and life of a person with a history of cancer *beyond* the acute diagnosis and treatment phase (5). Survivorship research seeks to identify, examine, prevent, and control adverse effects of cancer treatment utilizing integrated multi-disciplinary treatment to optimize the psychosocial, physiologic, and functional outcomes for cancer survivors and their families (5).

The research presented in this chapter reinforces the importance of examining the impact of cancer on children of different ages and developmental stages and within the context of family. The chapter also serves to orient the reader to the unique and sometimes subtle psychological, social, and behavioral effects of cancer on children and their families.

DEVELOPMENTAL CONTEXT

The boundaries used by theorists and researchers for classifying a "child" (as opposed to an adolescent or young adult) are varied. Some studies of pediatric cancer patients involve primarily elementary school-age children, while others combine younger school-age children with teenagers. Across this broad age range, the bulk of psychosocial research has been carried out with older school-age children. Very little work has been done with children under the age of 8 or 9 due in part to challenges related to literacy, human subjects' consent, and measurement. The diagnosis and treatment of cancer will be interpreted and experienced differently by children of various ages and life stages. These differences are reflected in the literature presented in this chapter.

FAMILY SYSTEMS

The growth of "family systems theory" (6) has emphasized how childhood illnesses, especially childhood cancer, may place psychological as well as physical strains on the family as a social system (7). In one of the first comprehensive studies of the family impact of childhood cancer, Chesler and Barbarin (8) suggested that childhood cancer is a "family disease" in that it "challenges the life course not only of the ill child but of the entire family." Kazak et al. (9) utilized Bronfenbrenner's social ecologic framework (10); the child is seen within the context of their environments; starting with the child's family, then health care team, extended relatives, schools, neighborhoods, and communities (9). This approach focuses on building a "therapeutic triad," joining the patient, family, and health care team within the larger social system to promote positive outcomes (9). The goal of the health care team in the therapeutic triad is to "join, focus, promote competence, and collaborate"

with patients and families (9).

Building upon previous research examining resilience within individual family members, there is emerging research around resilience and family-level processes and outcomes (11). This research supports ongoing monitoring of family functioning, with attention to the cultural and socioecologic contexts of the family (11). Ongoing surveillance of family functioning can increase awareness of opportunities for the health care team to offer family-level supports and services throughout a continuum of care that often lasts months and in some cases (e.g., leukemia) years (11). A subset of parents and siblings of oncology patients may experience increased depression (12), anxiety (13), and posttraumatic stress symptoms (PTSS) (14) compared with parents and siblings of healthy children. Specific sociodemographic factors, such as child age, maternal depression and anxiety, and lower family income have been identified as risk factors for worse cognitive outcomes, increased pain, and increased child depression and anxiety (15–17).

INTELLECTUAL ISSUES

Knowledge about Cancer, Treatment, and Life Threat

At the diagnostic stage, and immediately thereafter, children may experience stress in understanding the seriousness of the situation and in dealing with uncertainty. How do children become aware that they have a condition they ought to worry about? Sometimes parents or staff members tell them directly, but information may not be complete, may be delayed or not presented in a manner appropriate to the developmental stage of the child. Children and family members whose primary language is not English may struggle with simply understanding what hospital personnel are telling them, let alone the complexities and implications of impending medical procedures and treatment. Also, children will astutely draw conclusions from the many cues consciously or unconsciously exhibited by parents, family members, friends and medical staff and by reading between the lines of what is said directly and what is whispered out of earshot. Many children note the rapidity and drama with which they are hospitalized; siblings are allowed to stay home from school in order to be at the hospital; grandparents travel long distances to come to the bedside; friends and relatives visit in large numbers; nurses and doctors visit often; and, almost everyone is extra attentive or looks scared or sad.

Siblings of all ages struggle as well. Recent qualitative research suggests dominant themes of siblings' desire for information and involvement in their sibling's care and support around the changing roles within the family (18). There is need for anticipatory grief, strategies to deal with the emotional "rollercoasters" of hope and disappointment, and effective communication around the sibling's diagnosis (18). Siblings will benefit from social, emotional, and instrumental support (18). Including

siblings in family meetings and providing them with age-appropriate information can help keep them informed and connected, *and* provide opportunities to engage with and assess siblings for their own psychosocial needs (19,20).

PRACTICAL ISSUES

The Hospitalization Experience, Including Pain and Painful Procedures

Children with cancer have been found to experience high levels of symptom burden and suffering throughout their illness (21). Early integration of pediatric palliative oncology (PPO) principles by an integrated care team with all high-risk patients and families can help facilitate holistic continuity of care (22). Pediatric cancer treatment often involves multiple administrations of highly aversive medical procedures such as lumbar punctures, bone marrow aspirations, spinal taps, and venipunctures over a prolonged period of time. Surgery, chemotherapy, radiation, repeated hospitalization, tests, and injections all debilitate the child physically and emotionally. According to recent systematic review, the most commonly studied psychological interventions for managing pediatric distress and pain with needle procedures were distraction, hypnosis, and cognitive behavioral therapy (23). Additionally, higher levels of parental self-efficacy around being able to keep their children calm during medical procedures were correlated with lower levels of child distress and increased child cooperation during procedures (24). In addition to pain, the illness and the side effects of treatment may disrupt family life, school attendance, friendships, and social activities. Psychosocial interventions have been developed to support adolescent survivors of childhood cancer and their families. The Surviving Cancer Competently: An Intervention Program (SCCIP) is a 1-day family group intervention that combines cognitive-behavioral and family therapy approaches (25). The goals of SCCIP are to reduce symptoms of distress and to improve family functioning and development (25). Additionally, research around social network development following a child's cancer diagnosis suggests that support is received from pre-existing social connections, as well as new connections with other cancer families (26). Health care professionals served as "network brokers," fostering the development of new connections among families and connecting parents with supportive resources (26).

Managing and balancing family home life and care for a child with cancer are the ultimate challenge for parents. Parental chronic stress has been associated with decreased levels of emotional, physical, and social functioning among pediatric patients (27). Many parents have indicated that uncertainty about their parent role and anticipating their child's distress during medical procedures are primary sources of stress, with uncertainty about the parenting role being associated with other measures of psychological distress (28). Parents may experience loss of control and restriction

of their autonomy throughout the process of their child's treatment (29). Parental caregivers have identified that the most helpful action of health care providers was receiving timely, accurate and carefully delivered information about their child, while the most helpful actions of family and friends were gestures of support and understanding (29).

Adherence to Treatment

Nonadherence to prescribed treatments constitutes one of the most frequently encountered impediments to therapy administration in children with cancer, particularly adolescents. Treatment abandonment, defined as the failure to start or complete medically indicated curative therapy (30), is the most common cause of treatment failure for children with cancer in many low- and middle-income countries (31). Recent discussions suggest that the rapport between medical staff, parents, and children may be a key ingredient in overcoming resistance and promoting adherence to medical regimens. Adolescents have indicated a spectrum of preferred decisional roles, which might shift depending upon situational and social contexts, with the most commonly preferred being active involvement, although a shared decision-making approach was still valued (32). Additionally, it is helpful to remember that the cognitive and emotional capabilities of youth are still forming until 25 years old, including their reasoning abilities (33). Adolescents expressed an appreciation of parental presence, clinician guidance, and family insight (32).

Cultural differences between patient, family, and medical staff also may interfere with treatment administration. In our multicultural society, there are varying life experiences, beliefs, value systems, languages, notions of health care, and religions (34). To engage and support families during potentially the most vulnerable time in their lives, we must practice with cultural sensitivity and cultural competence, bridging care and patient need as a vital link in communication with patients and families (34).

School

While most patients are able to resume school activity in early outpatient phases of the treatment, complexities of treatment regimens, frequency of routine follow-up, disease status, neutropenia, and infections can contribute to school difficulties (35). Hospitalizations result in missed school days and often necessitate assistance with schoolwork (obtaining assignments, learning materials, completing homework) (36). Many children's hospitals have inpatient schools where teachers help patients keep up with their schoolwork, often communicating with the child's teachers to obtain assignments.

Barriers to school reentry include changes in the child's appearance, cognitive

abilities, emotional status, and physical activity, and misconceptions by peers and school personnel about cancer (37). Childhood cancer survivors as a whole are more likely to utilize special education services when compared to sibling controls, especially those diagnosed at a young age (38,39). Survivors of brain tumors and childhood acute lymphoblastic leukemia (ALL), especially those with a history of cranial radiation, often experience higher rates of neurocognitive dysfunction and educational needs (38,39). They may experience deficits in attention, concentration, memory, handwriting, math, and organizing or sequencing of tasks (40). Recent exploration of neurocognitive assessments of pediatric brain tumor survivors and ALL survivors suggest that brain tumor survivors with deficits exhibited a profile suggestive of global executive dysfunction, while affected ALL survivors tended to demonstrate specific rapid naming deficits (41). Due to the complexities and risks of neurocognitive deficits among survivors, there is increased clinical and research focus on neurocognitive assessment for survivors of pediatric brain tumors (42). A brief neurocognitive screening measure, The Lebby-Asbell Neurocognitive Screening Examination (LANSE), has demonstrated preliminary reliability and validity for youth with brain tumors (42). The advancement of neurocognitive screening tools can help inform late-effects intervention planning (41).

INTERPERSONAL ISSUES

Peer Relationships

Many youth and adolescents experience isolation from peer and family support networks when battling cancer during their formative developmental years (43). Peer support is integral in coping with these challenges, yet cancer treatment can create isolation from friends and family (44). There are many factors that can impact the social functioning of childhood cancer survivors, including biologic effects of treatment, changes in physical appearance and functional impairment, and family factors such as parental overprotection (45). However, there is great heterogeneity in the literature around the social functioning of childhood cancer survivors, with some studies suggesting reduced social engagement while other studies have found no significant differences between childhood cancer survivors and their peers on measures of social functioning (45). Future research around potential strengths in peer relationships or areas of growth in friendships that result from cancer would help better inform the interpersonal impact of cancer in youth (45). Additionally, interventions should be designed and promoted to foster peer engagement and reduce isolation throughout treatment and beyond (45).

EMOTIONAL ISSUES

Distress

As might be expected, children and their families experience and exhibit emotional and behavioral problems during the initial phases of diagnosis and treatment, with investigators reporting behavioral and emotional disturbances manifested in increased anxiety, depression, regression, and withdrawal among children in treatment for cancer. For instance, Cavus¸og˘lu (46) reports that rates of depression for both males and females aged 9 to 13 and at least 1 year after initial diagnosis were significantly higher than in a healthy age-matched control group and that rates also were significantly higher among patients in treatment than those off treatment and in remission. In contrast, others report few emotional or behavioral problems in children with cancer and demonstrate normal psychosocial functioning during treatment administration (35).

To help monitor distress and proactively support youth and families, brief distress screening tools can be integrated into routine social work and/or nursing intake assessments in multidisciplinary health care settings (47). Review of the literature by Kazak et al. (47) has identified specialized distress screening tools for pediatric cancer: the Distress Thermometer (DT) and the Psychosocial Assessment Tool (PAT). The DT is a very brief unidimensional measure of distress (48) that was developed for screening with adults, and has been adapted for use in pediatrics with a rating scale of faces for 2- to 4-year-old children and with developmentally appropriate words for 4- to 6-year-old children (49). The PAT (50) is a brief parent report measure that screens for key areas of functioning associated with adjustment. The PAT maps onto the Pediatric Preventative Psychosocial Health Model, a conceptual model developed to distinguish among levels of risk (universal, targeted, or clinical risk (51)). With enhanced knowledge of youth and familial risk for adjustment concerns, providers can help to determine what types of supportive care interventions are indicated.

In addition to the research suggesting that for many school-age children emotional problems are either of short duration or not severe, recent work suggests that some children surviving cancer may be emotionally stronger than their healthy peers, and may be significantly more emotionally coherent and centered than they themselves were prior to their cancer treatment. Prior research suggests that some survivors of childhood cancer experience or manifest positive adaptation, or “posttraumatic growth” (52). Barakat et al. studied posttraumatic growth (PTG) following childhood cancer survival, and their findings suggest that the majority of adolescent survivors of childhood cancer and their parents reported PTG, measured as positive changes in self, relationships with others, and plans for the future (53). Families identified multiple positive changes, with endorsement of growth notably high for how they think about their life, how careful they are, their plans for the future, how they treat others and how relatives and others treat them (53). Interestingly, among adolescent

survivors, there is a likely interaction between PTG and PTSS and age at diagnosis, such that those who were older than 5 at diagnosis reported more PTG and PTSS than those were under age 5 (53). Adolescent survivors who are better able to remember their treatment experiences appear to appreciate both the challenging and adaptive impacts of cancer on their lives (53).

Among siblings, significant internalizing problems, such as emotional and social withdrawal, anxiety, feelings of guilt, hopelessness, shame and sadness; or externalizing problems, such as anger, noncompliance or other acting-out behavior, have been reported (54). Recent meta-analysis of psychological functioning of siblings in families with chronic health conditions suggest that siblings of children with highly intrusive and/or life-threatening chronic health conditions are at higher risk for psychological concerns (55). Additionally, siblings have been found to be more vulnerable to internalizing problems (55). Siblings also have been found to express fears, worries, and concerns that their brother or sister might not survive their illness (56), and they experience anxiety around a lack of communication within the family (38). Notably, Havermans and Eiser (56) found that siblings in families that scored high on communication also were more likely to report worrying about death of their sibling than did siblings in families scoring low on communication. Over time, impaired psychosocial functioning and quality of life improves for most siblings, although adolescent siblings experience more impaired emotional and social functioning when compared to younger school-age siblings (57). Younger siblings' positive self-attributes also appear to be less negatively affected than older siblings' self-attributes (55).

EXISTENTIAL/SPIRITUAL ISSUES

Uncertainty

Mishel (58) defines uncertainty within the context of illness as the "inability to determine the meaning of illness-related events," which is brought about by "unpredictable and inconsistent symptom onset, continual questions about recurrence or exacerbation, and unknown future due to living with debilitating conditions." While many aspects of cancer and treatment in children remain uncertain (survival, effectiveness of treatment), children may not necessarily characterize themselves or their lives as uncertain. For example, in a study involving 9- to 12-year-old children with a variety of cancer diagnoses, Stewart (59) reports that these children quickly came to view their lives as routine and ordinary despite the unpredictable nature of the course of their illness. They described a process of getting used to cancer that allowed them to keep their focus on the ordinary nature of their everyday lives within the uncertain context of their illness, thus providing important insight into children's psychological adjustment to life-threatening illness. Although children with cancer

live with symptoms of treatment on a daily basis, they also suggest that the symptoms are an integral part of overcoming cancer and do not expect complete symptom relief (60). While they suggest that one never gets used to symptoms and that symptoms contribute to discomfort and suffering, there also exists an attitude or belief among some children that they must exchange short-term pain for long-term gain, that they must feel a lot worse before they can feel better (60). This is all part of what Woodgate and Degner (61) theorize and call "keeping the spirit alive."

COPING WITH CANCER

Normalizing the Experience

Children with cancer sometimes feel that they are living between two social worlds, dealing simultaneously with normal social situations and with medical treatment in the hospital environment. Even as children in remission readjust to their social environment, they still need to continually enter the hospital environment for checkups and treatments. Yet, young people with cancer overwhelmingly report that their primary goal is resuming a sense of normalcy in their life as soon as possible. Health care providers can help through providing developmentally appropriate, flexible services that promote a sense of normalcy (62).

Normalizing School, Education, and Social Lives

As children with cancer undergo treatment, they also continue with their lives. For children between the ages of 6 and 18, school attendance is an important part of life, and a vital social and developmental activity. School represents the continuation of children's normal life as well as the primary source of social activity. Yet, parents of youth whose health is seen as fragile may be reluctant to entrust their child's care to the school. Some treatment centers have special programs for school personnel to learn about cancer, while others have members of the treatment team visit the school on request. In other cases, parents become responsible for communicating directly with school personnel.

Normalizing participation in school and social life involves participating in or avoiding social involvement and linking to friendships. Youth may struggle with disclosure of their diagnosis to peers, and fear of acceptance can limit social engagement with peers. Thus, participation in oncology camps, cancer survivor day picnics, and family retreats offer opportunities for life experiences that promote successful achievement of age-appropriate developmental tasks.

Students with cancer or a cancer history whose medical problems adversely affect their educational performance are considered to have a disability—to be "other health impaired," and as such entitled to receive needed special educational services

(40). For children whose physical conditions place them at risk of further health problems, homebound education may be called for. Homebound instruction, while often indicated for patients at risk for exposures to infection in public, was recalled by 8- to 17-year-old off-treatment survivors as being academically inadequate and socially isolating (63). Throughout cancer treatment and beyond, youth should be monitored closely to allow for early intervention of support and services to foster educational success (38).

Communicating with Children about Cancer

There is a wide variety of opinion and practice regarding what and how much should be told to a school-age child about their diagnosis, treatment, and prognosis. The Psychosocial Committee of the International Society of Pediatric Oncologists (SIOP) recommends full disclosure to the child, after or during a conference with the parents (64). Current research indicates that both the child's age and their preferences for information are associated with psychosocial outcomes. Children often need to have conversations on their own time frame, and clinicians can foster time for children to share their hopes, expectations, and worries by being attentive and supportive throughout the treatment process (65).

Coping Styles

Questioning, cheerfulness, denial, talkativeness, depression, humor, withdrawal, optimism, and low energy level all may be initial coping responses to therapy in children. These strategies tend to change and alternate over time as children pass through various stages of therapy and off-treatment survivorship (35). Hope theory, as developed by Snyder (66), can be a useful framework to foster positive psychological adjustment in children with cancer through focus on pursuit of goals (67). Hope may influence how stressors are appraised, and clinicians can help guide children with cancer to identify and pursue a variety of goals, to use active coping strategies, and to modify their appraisals of their cancer diagnosis (67). Recent research suggests that increased hope also predicts improved quality of life in children with cancer (67).

Assessment of survivorship needs among young adult survivors of childhood cancer emphasized the need for educational and psychosocial resources, particularly technology-based resources (68). The Children's Oncology Group conducted a review of the psychosocial late effects of pediatric cancer to inform the development of their Long-Term Follow-Up Guidelines (69). Their review suggests that while many survivorship studies continue to specify risk factors for anxiety and PTSS/posttraumatic stress disorder, other outcomes, such as developmental, interpersonal, and familial factors, appear to be emerging in importance (69).

SOCIAL SUPPORT

Many parents seek education and support to help them identify, express, and master the powerful feelings evoked by the difficult events of childhood cancer. Some need only validation of their feelings or that they are managing life adequately given the circumstances. Others need more intensive therapy or emotional support from trained mental health professionals. For many, parental hope is integral to helping parents cope with the illness experience, as is social and family communication (70). Kamihara and colleagues interviewed parents of children with cancer around their hopes for their children in the face of prognostic information (71). Despite concerns about prognosis, parents expressed a wide range of hopes for their children, from hopes related to cure or treatment response, to quality of life, normalcy, love, good relationships, to hopes for their siblings and for better treatment of future children with cancer (71). Many parents were able to acknowledge that their hopes differed from what was likely to happen (71). These findings suggest that clinicians can utilize conversations around hope as a means of joining the family on their journey (71).

Receiving peer support from friends, from other parents of children with cancer and from community-based organizations composed of health professionals or laypersons is critically important (72). Locally organized parent groups exist in over 300 communities and medical sites across the United States. Some are large and formally organized, with bylaws, elected officers and nonprofit legal status, and others are small and informal gatherings. Some include members of the medical staff and others are exclusively parent-led and attended. While not all (nor even a majority) of parents of children with cancer become active members of such groups, those who do report many benefits. The American Childhood Cancer Foundation (formerly Candlelighters) remains the preeminent national clearinghouse and resource for support groups for families of children with cancer (www.acco.org).

Involvement in supportive social networks and having opportunities to express feelings and worries related to cancer may improve parents' adjustment to illness over the long term (73). For example, some parents experience improvements in emotional functioning and adjustment from participating in professionally lead support groups or nonprofessional parent-led self-help groups; supportive programs and interventions appear to offer important coping skills for parents of children in treatment. Current literature also reinforces the importance of support groups and camps for siblings and opportunities for peer involvement with other siblings. Camp facilitates participation in activities that improve knowledge, self-esteem, and social confidence (74).

ADVANCES IN WEB-BASED TECHNOLOGY

Virtual (or online) support communities have become a prevalent mechanism for accessing social support and health care resources, particularly among adolescents and young adults (75). However, factors of access, sociodemographics, computer literacy, and health literacy have been found to significantly impact Internet usage (76). There remains a multitude of questions around Internet usage, such as the opportunities and pitfalls of electronic communication between patients and health care providers, how to measure efficacy of virtual support communities, and overall, how to optimize the positive effect of the Internet without disadvantaging others (76).

There is also a telehealth movement creating change in the way that mental health services are delivered worldwide and reducing environmental and systemic barriers to care, such as geographic isolation and limitations of time and resources (77). Wakefield et al. in Australia are piloting the use of an online parent-targeted cognitive behavioral intervention, CASCAdE (*C*ope, *A*dapt, *S*urvive: Life after *CA*nc*E*r), to improve the quality of life in families of pediatric cancer survivors (78). Variables such as additional psychosocial support services and peer support are likely to be important in thinking about the efficacy of this intervention and web-based mental health interventions more broadly (78).

CONCLUSION

Cancer impacts youth within and across all systems in their life, including their families, health care teams, schools, neighborhoods, and communities. School-age children diagnosed with cancer enter a world of unfamiliar and threatening people and things, emotional confusion, physical discomfort, and pain. Diagnostic procedures are painful and scary, and the child often exists in the midst of a world of uncertainty—his own and his parents'. This uncertainly is escalated when parents and the medical staff fail to provide the child with information that is adequate, coherent, and tuned to an appropriate developmental level. Even with adequate information, young children often worry about their future, whether they will endure repeated hospitalizations and time away from home. Subsequent hospitalizations, of short or long duration, separate and often isolate the child from peers and schoolmates, as well as from the ordinary routines of family and neighborhood life. In addition, the long-term effects of the disease and treatments may compromise cognitive capacities and social or physical functioning (especially in the case of major surgery or radiation to critical organ systems).

Parents may experience loss of control and restriction of their autonomy throughout the process of their child's treatment. Parents of children diagnosed with cancer typically experience shock and surprise. The stress of having a child diagnosed with a frightening and potentially fatal or disfiguring disease is escalated by the necessary entry into the culture of tertiary care medical facilities and their language, jargon, and status systems. Parents' central role as a parent is to protect

their children from harm, and a diagnosis of cancer in a child challenges the core definition of parentage. Parental caregivers have identified that the most helpful action of health care providers was receiving timely, accurate and carefully delivered information about their child, while the most helpful actions of family and friends were gestures of support and understanding.

As all families experience distress in the face of their child's cancer diagnosis, there is increased focus on universal psychosocial screening for youth and families at the time of diagnosis with cancer. Distress screening tools can be integrated into routine social work and/or nursing intake assessments in multidisciplinary health care settings. With enhanced knowledge of youth and familial risk for adjustment concerns, providers can help to determine what types of supportive care interventions are indicated. Parents are often called upon to spend time in the hospital with the ill child, and for many the child's response to the illness raises concern about maintaining normal childrearing practices and discipline. In addition, parents are faced with balancing the competing needs of the ill child, family chores and relationships, and employment requirements. If employers are not responsive to these concerns, the family may face added financial stress. Maintaining normal and satisfying family routines and relationships often is difficult under these circumstances. Siblings often feel left out or overlooked, marital stress may occur (especially when mothers and fathers cope differently and with difficulty) and relationships with parents' parents and friends may also suffer.

Patient experiences need to be understood within the context of survivorship, across the lifespan, to optimize the psychosocial, physiologic, and functional outcomes for cancer survivors and their families. Longitudinal research is indicated to help assess child and family coping over time as the child progresses through different illness stages and developmental levels. The infusion of web-based technology in mental health service delivery may provide opportunities to reduce environmental and systemic barriers to care. Recent research around parental hope suggests that clinicians can utilize conversations around hope as a gateway toward talking about what is possible and as a means of joining the family on their journey. Joining families in their cancer journey has also increased our awareness of resilience and PTG among childhood and adolescent cancer survivors. The future holds great opportunity to support, empower, and enhance the lives of children and youth with cancer during their treatment and beyond.

CHAPTER 7.2.2 ■ THE ROLE OF THE CHILD AND ADOLESCENT PSYCHIATRIST ON THE PEDIATRIC TRANSPLANT SERVICE

STEVEN C. SCHLOZMAN AND LAURA M. PRAGER

INTRODUCTION

Both solid-organ and bone marrow transplant procedures have become increasingly successful over the last 30 to 40 years. For example, survival outcomes for pediatric renal transplant are over 95% at 5 years (1). No longer focused solely on the patients' survival, transplant services have begun to recognize the importance of the psychosocial development of those patients whose lives were saved but permanently altered, and their risk for an emotional backlash that parallels the potential for medical complications. In addition, as young transplant recipients live longer, they (like their typically developing peers) struggle with the desire for increasing autonomy from parents and caregivers, a passage that can be fraught with challenges given the possibly life-threatening implications of nonadherence to treatment regimens, experimentation with substance use, or other risky behaviors.

The child and adolescent psychiatrist (CAP) who works with pediatric transplant patients is ideally suited to assess and manage emotional sequelae of transplantation including, among other things, posttraumatic stress disorder (PTSD) from the procedure itself, adjustment to the ongoing risk for infection and/or rejection as well as to the ever-present potential for developing a malignancy, neurocognitive changes, and questions and concerns surrounding sexuality or fertility. The CAP can also help to guide these young, chronically ill patients through the developmental milestones that attend the transition from adolescence to adulthood. Furthermore, as most psychiatric disorders emerge during adolescence and young adulthood, the child and psychiatrist who works on a pediatric transplant service can assist with the diagnosis of emerging psychiatric disorders and devise psychopharmacologic treatment regiments that do not compromise existing immunosuppressive regimens.

In this chapter, we will summarize the psychiatric aspects of pediatric solid-organ and bone marrow transplant patients. We will focus on the evaluation and preparation of patients and their families for the procedure itself, on how to work with the patient and family during and immediately following the procedure, and on the long-term management of these patients as they move forward in their lives. In many ways, pediatric transplant psychiatry epitomizes the fundamental aspects of good consultation–liaison work. The principal challenge for the transplant psychiatrist is balancing the dual role of helping the patient and family maintain a normal developmental trajectory while at the same time assisting the transplant team

with the often charged and intense emotions that accompany working with these young patients.

Patients who face either solid-organ transplant or bone marrow transplant are gravely ill and struggling with life and death issues. Transplants are a viable option when other treatment modalities cannot prevent death or progressive, debilitating illness. Depending on the patient's age and developmental stage, he or she will often be acutely aware that organ failure is life threatening, yet unable to weigh the risks and benefits of transplantation. The risks of the surgery itself are even difficult for adults to contemplate, as is the meaning of the commitment to a lifetime of medications with both short- and long-term side effects. Patients and their families will wonder about issues as immediate as whether academic and developmental progress will continue unabated, and as distant as whether or not fertility will be at risk. In this setting, both the patients and their families are usually under enormous stress. Together they must process this complex information and then make a decision about whether or not to proceed with a potentially life-threatening and most certainly life-changing treatment. The CAP on the transplant service can be instrumental in identifying the cognitive and emotional level of the patient based on age and stage, placing the child and his or her needs within the context of a family dynamic, and communicating this information to other members of the team. The CAP can also assist other members of the team to appreciate the families' degree of distress as well as make suggestions for how to discuss potential outcomes with both the child and the parents.

Transplantation is a final common pathway for a group of heterogeneous and not always related conditions. This poses a special challenge to the child psychiatrist working with the transplant team. To be effective, the child psychiatrist must have an understanding of the medical and surgical components of the underlying disease as well as an understanding of the risks and benefits of the transplant itself. He or she must then tailor any treatment to the temperament and pre-existing psychological and developmental challenges facing the child and the family, keeping in mind the inherent limitations posed by both the disease and the treatment. As many patients are quite young, there is the added challenge of balancing the involvement of an extended family and multiple systems of care. The work is complex but immensely rewarding.

IMMUNOSUPPRESSIVE MEDICATIONS

Immunosuppressive medications are still the mainstay of prevention of graft rejection, and many patients experience neuropsychiatric side effects from those medications. The calcineurin inhibitors such as cyclosporine and tacrolimus and the corticosteroids have been associated with anxiety, depression, agitation, delirium, paranoia, cognitive changes, and worsening of pre-existing psychiatric conditions. These effects will be discussed in detail below. The transplant psychiatrist must be

aware of the potential for these side effects as well as for the interaction between these agents and psychotropic medications.

Case Illustration 1: Side Effects of Immunosuppression

A 13-year-old boy with a history of autoimmune hepatitis and subsequent hepatic failure received a deceased donor liver transplant at age 12. Before his liver disease and surgery, he carried the psychiatric diagnoses of ADHD and an atypical mood disorder, and was treated with stimulant medications and atypical antipsychotics to prevent his often aggressive outbursts. Given the severity of his psychiatric disorder, his medication was continued throughout his perioperative course. However, after his transplant, he developed significant emotional lability that correlated with the addition of prednisone as a necessary part of his immunosuppressant regimen. This behavior was managed by increasing dosages of his atypical antipsychotic medications. As atypical agents are metabolized in the liver, increased monitoring of his liver function tests was necessary to ensure that the added psychotropics were not further compromising his graft.

Many transplant recipients are on multiple agents, and these may affect each other with significant neuropsychiatric sequelae (refer to Chapter 6.1.1). The transplant psychiatrist may be the member of the team most likely to recognize these interactions given that vigilance regarding drug–drug interactions is a mainstay of psychopharmacology.

Case Illustration 2: Drug–Drug Interactions

An 18-year-old woman who underwent a deceased donor liver transplant for biliary atresia at age 2 presented to the pediatric transplant service for ongoing management of her transplant, as well as for care of her inflammatory bowel disease. Important psychiatric issues included diagnoses of depression and anxiety for which she was prescribed clonazepam and paroxetine. Her history was also significant for recreational marijuana use and a complex partial seizure disorder. Finally, she had persistent difficulties with medication compliance, often stopping her antirejection medications. After her arrest for possession at age 19, she abruptly stopped using marijuana, and almost immediately thereafter experienced another round of graft rejection for which she was admitted to the hospital with the assumption that she had stopped taking her medications. A low tacrolimus level made her insistence that she was indeed compliant all the more puzzling. The transplant service eventually concluded that the sudden withdrawal of marijuana likely increased gastric motility, such that she absorbed her immunosuppressing medication less well than before and thus was not able to maintain her graft without immediate treatment with steroids and a higher overall immunosuppressive regimen. Appropriate adjustments in

immunosuppressant dosages adequately addressed the problem, and the patient was able to maintain her graft.

Transplant as Trauma

There is mounting evidence that both bone marrow and solid-organ recipients are at risk for posttraumatic stress syndromes (PTSS) and in some instances will meet full criteria for PTSD. Mental health providers who work on transplant services need to watch for these symptoms, both in patients and in their families. A recent review by Stuber et al. (2) suggested that parental trauma was a strong predictor of patient traumatic reaction among medically ill pediatric cancer patients. Similarly, in pediatric transplant patients, new research stresses that the families' and patients' appreciation of the seriousness of the illness, regardless of how physicians tended to view the severity of the condition, is a potent predictor of pathologic stress reactions (3). There is also evidence to suggest that premorbid parent anxiety predisposes parents of children undergoing transplant to developing PTSD (4). In addition, it is possible that the extent to which parents feel traumatized correlates with the psychological and medical well-being of the pediatric transplant recipient (2,3). Finally, as one might expect, sudden events, such as abrupt rupture of esophageal varices in patients with portal hypertension, are associated with more traumatic responses than insidious serious illnesses, such as slowly progressive cardiomyopathies or a gradual decline in pulmonary function.

Trauma among medically ill children is further complicated by the fact that the child patients may perceive the treaters as perpetrators. This perception can extend to parents, given that parents are often called upon to enforce difficult and painful regimens. This poses a special challenge to the treatment team. Judicious use of anxiolytic medication and psychosocial interventions such as guided imagery and other relaxation techniques have all been useful in helping child patients tolerate difficult procedures and/or participate in their own treatment.

Finally, because avoidance is a core symptom of trauma, patients may be nonadherent with their medications or doctor's visits in order to avoid the negative emotional valence associated with these experiences. This response can occur in both pediatric patients and their parents. The team should be vigilant for trauma as an etiologic factor for nonadherence in this patient population (5).

Graft Rejection

For all patients who undergo transplant procedures, there exists a difficult equilibrium in allowing their children to develop and grow as normally as possible, while remaining constantly vigilant and increasingly anxious about the possibility of graft rejection. Graft rejection is not always obvious, though in some instances it is

preceded by a clearly worsening course. In other situations, however, possible graft rejection is discovered in routine laboratory tests, leading to an element of hypervigilance that both patient and parents can experience and that is neither helpful nor healthy. Medication nonadherence is frequent, especially in adolescents, and constitutes one of the most common causes of graft rejection. Studies of barriers to adherence in medication-taking among adolescents have identified that those patients who lack organizational skills have more trouble remembering to take medications, and that those patients with comorbid psychiatric illnesses such as mood disorders, anxiety disorders, or PTSD are also more likely to be nonadherent (6). The transplant psychiatrist can be helpful in identifying, assessing, and managing the risk for nonadherence. His or her unique understanding of transplant medicine may encourage a frank discussion by the patient and family about their heightened concerns about rejection and the ways in which strict adherence to the medication regimen and other recommendations of the treatment team can reduce that risk.

Comorbid Psychiatric Illness

Given the natural epidemiology of childhood psychosocial and psychiatric difficulties, there will inevitably be some children and adolescents who will suffer psychological difficulties not directly related to their transplant, but whose transplant will complicate effective treatment. For these patients, though no clear guidelines exist, keeping in mind drug–drug interactions, the means by which medications are metabolized, and the possible neuropsychiatric side effects of immunosuppressants are all important considerations. In general, one should prescribe psychotropic agents in lower initial dosages and monitor closely both the mental status examination and laboratory values that might suggest adverse drug effects. In addition, one cannot underestimate the effectiveness of supportive, psychodynamic, and behavioral interventions for some patients. Undergoing and living with a transplant is trying at best, and for children and adolescents, the therapist can help them cope with shaping an identity that is informed but not defined by their illness.

BONE MARROW TRANSPLANTATION—SPECIAL CONSIDERATIONS

Patients who require solid-organ transplant (heart, kidney, lung, liver) often see their disease as limited to that organ. Bone marrow transplantation, however, is performed for patients who have an underlying systemic illness, that is, cancer. As cancer itself carries particular emotional valence in our culture, patients receiving transplant procedures for malignancies may require extra attention given the associated stress that the diagnosis and all of its cultural signifiers can entail. Although some pediatric patients may receive solid-organ transplantation for cancer, this is less common than

for organ malformation or metabolic and autoimmune diseases. Additionally, the isolation associated with bone marrow transplantation is particularly harrowing for all patients, and attention to the developmental needs of these patients is crucial for their psychological and medical well-being.

THE PRETRANSPLANTATION PSYCHIATRIC EVALUATION

The CAP plays an important and complex role in the evaluation of the child who is approaching transplantation. Initially, the psychiatrist is responsible for conducting a thorough psychiatric evaluation of the patient and family. In addition, the psychiatrist must be familiar with the medical problems facing the patient, both before and after surgery, in order to educate the family about the risks and benefits or transplantation and to assess the family's ability to provide informed consent. The psychiatrist also acts as a liaison between the family and the transplant team. The family will need support, direction, and clarification of the transplant team's expectations and concerns. The team in turn will also need support, direction, and sometimes interpretation of the family's behavior. The psychiatrist may also serve to focus the team's attention on ethical conflicts that may arise, particularly those that involve directed living donation by a related or unrelated donor.

There are no universally accepted guidelines for the psychiatric evaluation of children who are potential candidates for organ transplantation. Some centers routinely offer an open-ended, face-to-face clinical interview with a mental health provider, some require formal psychological testing, and yet others rely on structured or semi-structured interviews. Not all transplant teams have psychiatric consultants. In many centers, psychologists and/or social workers complete psychosocial assessments. There are differences among transplant centers as to what constitutes an acceptable candidate for transplant. Common exclusion criteria include active substance abuse, active psychotic symptoms, suicidal ideation with plan or intent, history of self-injurious behavior or suicide attempts.

As with a standard psychiatric evaluation, the order and style of the interview is dependent on the child's age and developmental stage. With a prepubertal child, it is appropriate, perhaps even necessary, first to meet with the parents in order to get a coherent, longitudinal history. With the adolescent, it is beneficial to interview the child alone before meeting the parents in order to reinforce the primacy of the adolescent's concerns and feelings. At some point, it is imperative to meet with the patient and the parents/caregivers together in order to be sure that all parties hear (and hopefully understand) the same information and that all are in agreement as to how to proceed.

The pretransplantation psychiatric evaluation should be primarily diagnostic but can also be educational and, sometimes, even therapeutic. In addition to the developmental, social, educational, family, and past psychiatric history, the

evaluation should address the following aspects:

1. Screening of potential recipients for the presence of significant psychiatric illnesses such as mood, anxiety, or psychotic disorders, as well as potential learning disabilities or frank cognitive impairment
2. History of past or current drug or alcohol abuse, particularly in the adolescent patient

The question of past or ongoing substance abuse in adolescents facing transplant is particularly important and warrants further discussion. In adult liver transplantation programs, ongoing alcohol or addictive drug use is usually a contraindication to transplant (7). Most programs require demonstration of 6 months to 1 year sobriety. With lung transplantation programs, tobacco use is an absolute contraindication to transplant and, again, candidates must demonstrate that they have abstained from cigarettes for over 6 months. Adolescents are less likely than adults to have a longstanding problem with substance abuse but frequently they have tried recreational drugs or alcohol in social situations. Sometimes they drink heavily or smoke marijuana on the weekends with their friends. It can be challenging to help these young people understand that such behavior could jeopardize their eligibility for transplant and could, if it continues after transplant, precipitate failure of the allograft. Individual transplant programs are left to determine what degree of risk they are willing to tolerate.

Indeed, the issue of alcohol use among adolescent transplant recipients and candidates requires special attention. This is of course particularly important when discussing liver transplantation. Although there is ample evidence that many adolescents experiment with alcohol, the use of alcohol by liver transplant patients is potentially extremely dangerous. Because liver failure can be insidious and unpredictable, it is difficult to assess when and to what extent alcohol use is likely to contribute to liver dysfunction. For these reasons, most child psychiatric consultants for liver transplant services feel that they must explicitly convey to their patients the seriousness of alcohol use. However, lecturing to teenagers about the dangers of alcohol use is likely to be met with resistance and defensiveness. Normal adolescent drives toward independence, coupled with the adolescent's unique susceptibility to peer pressure, often lead to alcohol use even among patients who understand intellectually that their liver disease makes this behavior particularly dangerous and unhealthy. At the same time, most transplant services do not view occasional experimentation with alcohol as an absolute contraindication for future transplants in adolescent populations. We have found that frank, developmentally appropriate discussions with adolescent transplant patients about alcohol use are substantially more effective at quelling and preventing experimentation and use of alcohol. While alcohol use is not under any circumstances acceptable, especially in adolescents with liver disease, helping teens to grasp the limitations of their disease in as mature a matter as possible is the best way to ensure healthy behavior.

Adolescents with liver failure are not the only ones vulnerable to the effects of recreational drugs. Adolescents with other forms of end-organ failure are also prone to experimentation, use, and even abuse of alcohol and other drugs. Cigarette smoking is an absolute contraindication to lung transplant, but other drugs that suppress the respiratory drive also have the potential for lethality. As the time for transplant nears, it is often very difficult to know whether the adolescent with substance abuse issues has "reformed" and stopped using simply because he or she has become gravely ill or because he or she has passed through the experimentation phase and recognized the limitations of such behavior. Transplant teams usually hope that the latter is true, but that is not always the case.

Case Illustration 3: Substance Abuse

A recent high school graduate with cystic fibrosis (CF) was hospitalized in the setting of declining pulmonary function for a course of intravenous antibiotics and aggressive chest physical therapy. Her pulmonologist noted that her pulmonary function tests (PFTs) had declined precipitously since her last admission and were not improving with standard medical care. He asked the transplant team to evaluate her for candidacy. On psychiatric evaluation, the patient acknowledged that in the year prior to admission she had developed an addiction to oxycontin (oxycodone). She had had completed a drug treatment program and been "clean" for several months. The transplant team was aware of her difficulty but felt that her drug use was probably adolescent "experimentation." All agreed that she would die without a transplant. She subsequently underwent living donor transplant approximately 9 months later and recovered well following the surgery. However, several months after her transplant she was rushed to the hospital in respiratory distress secondary to inadvertent narcotic overdose. She struggled with intermittent abuse for many months thereafter before finally agreeing to join a methadone maintenance program.

3. Assessment of child's relationship with caregivers
4. Determination of the child and family's motivation for transplant

Because young children do not always have a full understanding of either the gravity of their illness or of the ramifications of transplant, it is their parents and/or other caregivers/guardians who "consent" to the surgery and postoperative care. Nevertheless, a verbal child patient must be able to "assent" to the surgery and be willing to participate actively in the treatment process. Both parent and child must be able to work together toward the common goal of transplant. If parent or child is not fully engaged in the process, then it is difficult for the transplant team to know how best to proceed.

Case Illustration 4: Whose Transplant Is It, Anyway?

An 11-year-old boy with advanced CF and no past psychiatric history was brought by his mother for a living donor pretransplantation psychiatric evaluation. Mother was worried that her son would die before he became ill enough to reach the top of the list for a deceased donor transplant. She herself volunteered to be a living lobar lung donor and she aggressively pursued other potential donors until she found one. On initial interviews, the patient was cheerful and appeared to have a good understanding of why his mother and a neighbor each wished to donate a lung lobe. In his final meeting with the transplant team pulmonologist, however, the patient curled into a ball on the couch, cried quietly, and refused to talk about the impending living donor transplant. Ultimately, the team decided that it was the patient's mother and not the patient who was the motivating force for living donor transplant. The child did not feel ready to have an elective transplant with his mother as a donor. The team reassured the family that the child's situation was not too dire and he could wait until he was ill enough to become eligible for a deceased donor transplant.

5. Evaluation of the child and family's ability to comply with treatment recommendations of caregivers

Candidacy for transplant demands consistent attention to and compliance with the recommendations of the treatment team. Pre- and posttransplant patients must take many medications every day; often they are asked to endure time-consuming and uncomfortable procedures such as chest physical therapy for patients with bronchiectasis or CF. The patient's willingness to adhere to the pretransplant regimen is an important determinant of their readiness for transplant and the complicated posttransplant regimen that follows.

Case Illustration 5: Compliance

A high school girl with end-stage CF met with the child psychiatrist as part of a standard pretransplant evaluation. The patient asked her parents to be present for the entire interview. The young woman was strikingly thin. The transplant psychiatrist asked the patient if her CF doctor had ever suggested that she have a G-tube placed for nutritional supplementation. The patient burst into tears and stated that she could never tolerate a G-tube even though she had been told that she could not gain weight regardless of how many calories she consumed during meals. She acknowledged, also, that she had been instructed to start continuous oxygen but had been unable to do that either because she was too embarrassed to be seen in public with a nasal cannula. The psychiatrist tried to explore with the patient other ways that she might improve her ability to adhere to the recommendations of her doctors but ultimately

had to deny her candidacy for transplant based on her history of noncompliance and her inability to adhere to the recommendations of her physicians.

6. Understanding of the social supports available to the family
7. Assessment of psychosocial stressors in the family, such as financial pressures or marital discord
8. Assessment of the patient and family's understanding of the risks and benefits inherent in transplantation
9. Determination of the ability of the patient and family to collaborate with the transplant team with the shared goal of improving the patient's quality of life

PSYCHIATRIC CARE OF THE PATIENT AT THE TIME OF TRANSPLANTATION

For patients undergoing bone marrow or solid-organ transplantation, the stress of the procedure and the resulting hospitalization can be particularly trying. In addition, in cases where deceased donor organs suddenly become available, families find themselves thrown into the hospital with little time to prepare. These aspects of transplantation require special attention by mental health clinicians, especially around the time of admission and during the ensuing hospital stay. However, as with the pretransplant evaluation, there are no clear guidelines detailing the most appropriate intervention. Some centers employ an educational approach, requiring patients and families to undergo orientation to the hospital well before the transplant itself. Other centers focus attention on the patient and family directly after the transplant takes place. We have found that discussing these options with patients and families and allowing them to choose is the best approach. As we have stressed, intervention should focus on individual needs and temperamental differences.

Once the transplant takes place, it is imperative that the transplant psychiatrist be available to the patient, the family, and to the transplant team. Issues such as abrupt mental status changes, acute anxiety, poor medical outcomes, and treatment team stress all are often part of the transplant psychiatrists' responsibilities. These responsibilities are best met by frequent visits with all parties, developmentally appropriate explicit discussion of unfavorable outcomes with the team and with the patient and family, and vigilance for increasing stress and frustration surrounding the posttransplant course. To the extent that families can be made aware of the possibility of difficult postsurgical courses, they will be likely to cope more effectively with whatever outcomes transpire.

WORKING WITH THE TRANSPLANT TEAM

Transplant psychiatrists work with and are part of large multidisciplinary teams. In

this setting the psychiatrist who evaluates the child or adolescent for transplant candidacy can sometimes come into conflict with the treatment team. Because many transplant patients endure lengthy hospital admissions, pediatricians (residents and staff), physical therapists, social workers and child-life specialists often form long-term and extremely close relationships with children and adolescents with end-stage organ failure. To these caregivers, referral for transplant evaluation represents an acknowledgment of the failure of current management and, at the same time, a plea for the only viable treatment option.

These children and adolescents may not meet criteria for candidacy for transplant for many reasons. Sometimes, the patient is referred for transplant when they are too close to death and would not be able to tolerate the actual operation. Sometimes, the patient and family may be denied on psychosocial grounds. Regardless of the reason for denial of candidacy, the treatment team may be disappointed and angry with the transplant team. This is particularly difficult when the patient is denied because of a history of nonadherence with medical care in the outpatient setting and/or lack of social supports. Sometimes in these situations, caregivers promise that the patient will "do better" and appeal to the psychiatrist to reevaluate the situation. It is often helpful for the psychiatrist to meet with the treatment team to review the evaluation and to let all involved share their feelings.

Case Illustration 6: Conflict among Caregivers

A high school student with CF was hospitalized frequently on the pediatric service for treatment with antibiotics and chest physical therapy. The patient lived with her mother and her older sister. Her mother was an immigrant who worked long hours and was not home during the day. Her older sister was frequently out of the house as well. The patient spoke English but the mother did not. The patient had a very hard time complying with her outpatient regimen of multiple daily medications, breathing treatments, and chest physical therapy. She had had frequent hospitalizations over the years due to nonadherence with her outpatient self-care. The CF staff had tried many times to effect change in her social situation, without success. When asked why she was not able to take better care of herself, the patient said that she was too embarrassed to go to the nurse during school hours to take her midday medications and that at night she preferred to go out with friends. When the psychiatrist interviewed the patient regarding her interest in and suitability for transplant, the question of compliance took on more importance. The patient insisted that she wanted a transplant and that she would try harder to do all of what the treatment team asked of her. The patient's mother felt that her daughter's health was in God's hands and that she could not do anything more to help her. The transplant psychiatrist, after discussion with the treating pulmonologist, agreed to a trial period of 6 months during which the patient would be monitored carefully on the outpatient basis to

assess compliance. Unfortunately, the patient was not able to follow a schedule at home for even a period of a few weeks and was soon readmitted to the hospital in respiratory distress. The transplant team ultimately denied her candidacy.

THE LIVING DONOR TRANSPLANT

As there are many more patients who need organ transplant than there are available organs, living organ donation has become much more widely accepted in the United States. Living donation is a viable option for kidney, lung, and liver transplants. Potential donors also undergo a comprehensive psychological evaluation as well as a medical workup in order to ensure full autonomy, informed consent, and the absence of coercion. In some centers, the child psychiatrist or mental health provider working with the transplant team plays a crucial role in the evaluation of potential living donors. In other centers, the psychiatric screening evaluation of living donors is cursory. Additionally, some centers stress the need for a psychiatrist other than the transplant psychiatrist to evaluate the donor candidate. In all instances, great emphasis is placed on the absence of coercion in these unique situations. Living donors may be biologically related to the recipient, emotionally connected but not biologically related, or unrelated and anonymous. Lung transplantation is unique in that two donors are necessary.

It is very common for a parent to volunteer to donate an organ or part of an organ to a child. In those cases, the issue of benefit to the donor, that is, preservation of the life of a child is incontrovertible. However, the psychiatrist must help the team to consider the well-being of other members of an immediate family if both a child and a parent have surgery simultaneously. The psychiatrist also has an obligation to the patient to ensure that the parents' motivation for transplantation is in the best interest of the child, both physically and emotionally.

Potential donors who are siblings also merit close attention during a screening evaluation. It can be very difficult for a sibling who is blood type identical to refuse to donate, particularly if one or both parents are ineligible. Even though a sibling might deny feeling family pressure, it undoubtedly exists. A lobectomy is a painful and potentially debilitating operation. Siblings who volunteer to be living lobar lung donors must anticipate a 4- or 5-day hospital stay followed by 6 to 8 weeks of recovery before they will be able to resume normal activities.

The screening evaluation of an unrelated but emotionally connected donor or of a donor who has no connection at all with the recipient can present other challenges. Families of transplant recipients often advertise for donors on the Internet or in local community settings. Donors often come with an incomplete understanding of the process and unrealistic expectations for the outcome. Sometimes donors expect payment; sometimes donors are actively struggling with psychiatric illness or substance abuse. Studies of kidney donors have shown that as many as 50% of donors

who presented themselves as completely sure that they wanted to donate, expressed ambivalence about donation on self-report questionnaires (6). Again, it is left to the individual transplant center to determine who will make an appropriate, unrelated donor.

NEUROPSYCHIATRIC EFFECTS OF IMMUNOSUPPRESSIVE MEDICATION

The risks of rejection and infection are constants in the life of a posttransplant child or adolescent. All transplant patients are maintained for the rest of their lives on immunosuppressive medications. These medications and their interactions with other agents can have significant neuropsychiatric side effects that can be difficult to distinguish from psychiatric illness and that can complicate any planned psychopharmacologic regimen. It is also important to remember that a child's pharmacodynamics and pharmacokinetics can be different. A child's hepatic metabolic rate is faster than that of an adult and, although pediatric kidney function is similar to that of an adult, children (specifically between the ages of 9 and 12 years) may have a higher glomerular filtration rate as well (see Chapter 6.1.1). Children tend to metabolize common psychotropic medications such as neuroleptics, anticonvulsants, antidepressants, and benzodiazepines more rapidly. However, any psychotropic medication that inhibits the cytochrome P450 IIIA3/4 isoenzyme system can potentially increase the levels of immunosuppressive medication. Conversely, some agents, including the herbal antidepressant St. John wort can be associated with decreased immunosuppressant levels and subsequent graft rejection. Some of the most common neuropsychiatric profiles of immunosuppressant agents are summarized in Table 7.2.2.1.

Cyclosporine (Neoral, Sandimmune) is a polypeptide derived from a fungus and is the mainstay of immunosuppressive therapy. Common adverse effects include nephrotoxicity, hypertension, hypomagnesaemia, hyperkalemia, gastroparesis, and hyperlipidemia. Neuropsychiatric effects are particularly problematic at high serum levels and include delirium, often accompanied by frank psychotic symptoms (auditory and visual hallucinations). These side effects often resolve spontaneously as serum levels decrease, but patients often have a clear memory of their hallucinations. Patients with central nervous system effects sometimes have periventricular white matter changes on MRI. Cyclosporine is metabolized in the liver by the P450 IIIA3/4 system; it is possible that the selective serotonin uptake inhibitors could increase its serum levels through inhibition of the cytochrome system, but this has not been convincingly demonstrated (8). Carbamazepine may decrease its levels through hepatic induction. Patients who undergo bone marrow transplants may be particularly vulnerable to the neuropsychiatric toxic effects of cyclosporine (9).

TABLE 7.2.2.1

POTENTIAL PSYCHIATRIC SIDE EFFECTS OF IMMUNOSUPPRESSANT AGENTS

Immunosuppressant Agent	Description	Potential Psychiatric Side Effects	Laboratory Findings
Cyclosporin Neoral *Sandimmune*	Polypeptide fungal product	Delirium, auditory hallucinations, visual hallucinations, other psychotic symptoms	Side effects more prominent at high serum values and tend to resolve as serum levels decrease, SSRIs may increase levels, carbamazepine may decrease levels, herbal agents such as St. John wort may decrease levels, question of increased sensitivity to neuropsychiatric side effects among bone marrow transplant recipients
Tacrolimus *Prograf*	Also called FK506 or 5FK; macrolide antibiotic	Delirium, auditory and visual hallucinations, other psychotic symptoms, seizures, akinetic mutism	Side effects more prominent at high serum values and tend to resolve as serum levels decrease, MRI may reveal white matter changes in toxic patients
Mycophenolate Mofetil *Cellcept*	Suppresses T and B cell proliferation as adjunct immunosuppressant or for patients who cannot tolerate cyclosporine or tacrolimus	Anxiety, depression, sedation	
Muromonab-CD3 *OKT3*	Given immediately postoperatively to prevent rejection, monoclonal antibody that suppresses CD3 T-cell function	Aseptic meningitis, hallucinations during administrations	
Corticosteroids	Mainstay of most transplant regimens, usually started high and tapered over weeks to months, though many patients remain on small dose indefinitely	Increased appetite, anxiety, depression, hypomania, mania, paranoia	Often dose-related and resolve with lowered dose

FK506 (Tacrolimus, Prograf) is a macrolide produced by bacteria, and is also used as a primary immunosuppressive, sometimes as a substitute for cyclosporine. The neuropsychiatric side effects are similar to those of cyclosporine, including

delirium, seizures, and akinetic mutism. MRI scans may also reveal white matter changes in patients showing toxicity. Psychotropic medications such as the selective serotonin uptake inhibitors that inhibit the cytochrome P450 IIIA3/4 system can cause increases in serum levels of FK506 and must be used with caution.

Mycophenolate mofetil (Cellcept) suppresses T- and B-cell lymphocyte proliferation and is used as rescue therapy for those patients who cannot tolerate cyclosporine or FK506. It can also sometimes be used as adjunctive immunosuppression with cyclosporine. Central nervous system side effects can include anxiety, depression, and sedation.

OKT3 is a monoclonal antibody that is used in the immediate postoperative period to prevent rejection. It can cause aseptic meningitis. Patients can hallucinate during administration, but those symptoms usually abate fairly quickly.

Corticosteroids continue to be a mainstay of treatment for transplant patients. Very high doses in the immediate postoperative period are gradually tapered over several months. Most patients remain on a small daily dose of oral prednisone for the remainder of their lives. Their numerous side effects include weight gain, easy bruising, osteoporosis, hirsutism, affective lability, hypomania, or mania. Some patients can manifest psychotic symptoms at very high doses (10). The neuropsychiatric side effects are sometimes dose related and generally subside with gradual taper of medication. Sudden discontinuation of steroids can result in depression, irritability, or anxiety.

Case Illustration 7: Neuropsychiatric Effects of Immunosuppressives

A young woman with CF underwent bilateral living donor lung transplantation. After a rocky postoperative course, she stabilized and was transferred to the transplant floor. Although her overall condition continued to improve, the nurses often found her crying in her room and the psychiatrist was asked to assess her for a question of depression. On evaluation, the patient's mood was upbeat but she explained that she frequently burst into tears with the smallest stimulus. She felt that she was overreacting to "everything" but she could not help herself. She was embarrassed by how often she cried and puzzled because in between she did not feel sad. When asked about how things had gone for her in general, she reported that she had a vivid memory of her postoperative stay in the intensive care unit. She told the psychiatrist that she had had visions of people she knew coming and going although later her parents had told her that no one was there. She had a picture in her mind of her surgeon as a "prankster," dressed up in a costume. She remembered feeling incredibly fearful of him but also unable to help herself. The patient was relieved to learn that her affective lability was most likely secondary to her high-dose steroids and that her "hallucinations" were also a side effect of the cyclosporine treatment.

LONG-TERM PSYCHIATRIC CARE OF THE PEDIATRIC TRANSPLANT PATIENT

Transplant patients are typically followed closely by the transplant team for the remainder of their lives. They frequently have medical and surgical complications, they sometimes require a second or even a third transplant, and they often suffer significant psychological distress as they attempt to grapple with the long-term implications of their disease. Because of this, the transplant psychiatrist continues to play an important role. Management of all of these issues again calls for the careful reckoning of both psychiatric and nonpsychiatric phenomena. For example, a change in mental status may be secondary to a medication effect, a metabolic encephalopathy, a seizure disorder, a newly presenting psychiatric illness, or a combination of some or even all of these issues. Again, the medical expertise of the CAP makes him or her ideally suited for these complicated issues.

Additionally, as we mentioned above, psychiatric illnesses can occur either as a function of the transplant, or as unrelated conditions and problems such as mood disorders, anxiety disorders, and PTSD more common in pediatric transplant recipients than in their peers who do not suffer from chronic health problems (6).

CONCLUSION

As transplant procedures have become more successful, transplant teams have increasingly embraced the notion that the fundamental goal for young transplant patients is assuming the most normal life possible in spite of the obstacles that their diseases potentially pose. Transplant patients play on soccer teams, go on dates, graduate from school, and often want most of all to be thought of as an ordinary child or adolescent. Empathy for this desire, coupled with the simultaneous vigilance for the numerous problems outlined above, make the job of the pediatric transplant psychiatrist complicated, challenging, and undeniably rewarding.

CHAPTER 7.2.3 ■ PSYCHOSOCIAL ASPECTS OF HIV/AIDS

ROBERT A. MURPHY, KAREN E. O'DONNELL, AND SANDRA GOSSART-WALKER

The epidemic of infection with the human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome (AIDS) continues to be a major world crisis affecting the physical and psychiatric health and well-being of tens of millions of persons. According to estimates from the Joint United Nations Programme on HIV/AIDS; by the end of 2012, approximately 35.3 million people, including children, were living with HIV infection with only 260,000 new infections compared to 600,000 reported in 2005 (1). New HIV infections fell by 33% overall and by 52% for children around the world between 2001 and 2012.

In the United States, 1996 marked a major turning point in the epidemic, when the introduction of new therapies and combination therapy slowed the progression of HIV/AIDS for children and adults and led to an increase in the number of persons living with HIV infection. With successes in the prevention of mother-to-child transmission (PMTCT) in the United States (2) as well as effective drug therapies for those who are infected, HIV/AIDS now disproportionately affects women and minorities who are adolescents and young adults. The 2010 Centers for Disease Control and Prevention report indicated a sharp increase in HIV/AIDS among youth with 26% of new infections in the 13 to 24 age group, accounting for approximately 50,000 new cases annually (3). In the United States, it is estimated that 50% of HIV-infected youth do not know they are infected.

Both HIV-infected and HIV-affected children live in a world of stigma, grief from family deaths, multiple transitions in caregivers, and many other potentially traumatic experiences (4). With the highest incidence globally, adolescents represent a fast-growing population, presenting new needs for their medical and psychological care reflecting the shift from the focus on infants and younger children earlier in the epidemic (5).

PREVENTION OF MOTHER TO CHILD TRANSMISSION

Despite recent advances in PMTCT, early diagnosis in infancy, and effective drug treatments for children and adults that reduce mortality and morbidity from HIV/AIDS, there remains a gap between high (HIC) and low- and middle-income countries (LMIC) in identification, prevention, and treatment successes. The contrast is particularly true for children who, without early identification and treatment, will often die in the first years of life (6–8). Ninety percent of youth with HIV/AIDS live in sub-Saharan Africa, where access to antiretroviral therapy has increased but by less than 20%. Only a small proportion of HIV-infected children in LMIC receive

treatment (28% relative to 58% for adults) (1), in part because of persisting low rates of HIV testing and diagnosis (9,10). Between 2011 and 2012, the reach of PMTCT programs increased from 57% to 62%. Areas in which PMTCT programs are readily available and affordable have shown a dramatic decrease in the rate of perinatally infected children, achieving the global goal of 90% by 2015 (11). However, prevention programs in many LMIC countries are still challenged by program access for pregnant women, availability of drug treatments, reluctance to be identified with HIV/AIDS, and adherence to treatment (12,13).

Adolescents and Risk

Throughout the world, there is an increasing focus on children and adolescents who are the age cohort experiencing the highest rate of new infections. When effective treatments are available, children with HIV infection are living into adolescence and adulthood (14) yet, challenges related to illness, medication adherence, and mental health symptoms persist (15). Although some now refer to HIV/AIDS as a chronic illness, youth who are perinatally infected face unique challenges including the association of sexuality and danger, illness, and stigma. Surveillance data indicate that adolescents who were perinatally infected youth are more likely to be from ethnic minority backgrounds, contend with poverty, and live in disadvantaged neighborhoods and communities. They may, along with other family members, struggle with psychiatric and substance abuse problems, and tend to have significantly more school problems (14,16–19).

Newly infected adolescents face stressors that may be different from their perinatally infected peers. Some studies have shown that those infected during adolescence report more frequent and severe stressors, including family financial problems, parental substance abuse and conflict, and family loss and death (20). They are more likely to be acutely ill with a range of psychiatric problems and risk behaviors (e.g., unprotected sexual activity, substance abuse). Living away from home, they may lack the social or financial support of their earlier years (18,21). Due to stigma and secrecy, they may not confide in peers who comprise the majority of their social contacts.

Whether infected perinatally or during adolescence, youth with HIV/AIDS enter adolescence with developmental challenges that are similar to other adolescents, albeit in a context fraught with health risks. As they begin romantic and sexual relationships, their sexual behavior is complicated by their HIV status and the risk of transmitting the virus to others. As the proportion of HIV-infected and noninfected adolescents who are sexually active is similar, it may be that serostatus has little influence on sexual risk behaviors (22). Carter et al. (23) reported that most HIV-positive female adolescents expressed a desire for pregnancy indicating the importance of continued attention to vertical transmission of HIV to the newborn.

HIV-Affected Youth

The uninfected children of HIV-infected parents may have avoided infection due to the mother's antiretroviral treatment or the parent may have contracted the virus when the child was older. In either case, approximately 28% of HIV-infected adults have one or more children younger than 18 years (24). The unpredictable course of HIV/AIDS can limit parents' ability to provide consistent and stable care and perpetuates a sense of anxiety and dread among their children (25). Unlike HIV-infected children who are connected to regular, HIV-specialized care, affected children may have limited opportunities to talk about or receive support for anxieties and worries about their parents. A substantial proportion of HIV-affected children experience significant distress and psychiatric symptoms (26). Stigma due to HIV has been associated with poor psychosocial adjustment and delinquent behavior (27,28).

HIV INFECTED AND AFFECTED ORPHANS

Although new opportunities exist to decrease the number of children infected with HIV, the number of infected adults of childbearing age continues to increase in both HIC and LMIC, resulting in a still increasing number of children orphaned by the epidemic. With 16.6 million HIV orphans worldwide (90% in sub-Saharan Africa) (1), it is recognized that many who have been orphaned by HIV/AIDS do not thrive. Orphaned children in LMIC have high rates of unmet psychological needs (29) and scant access to mental health care (30). When treatment is available, rarely does it have prior evidence of effectiveness (31). Researchers advocate for translating evidence-based treatments (EBTs) from the high-income settings (HIC) in which they were developed to the geographical and cultural environments of resource-limited areas (32,33). World Health Organization guidelines (34) recommend structured interventions for bereavement and cognitive-behavioral therapy (CBT) with a trauma focus for post-traumatic stress (32). One study indicated that children ages 6 through 13 orphaned in a high HIV prevalence area exhibited a high prevalence of maladaptive grief that could be addressed through CBT (6).

Stigma and Disclosure

HIV has been affected by stigma since the early years of the epidemic when fears of contagion were pervasive. Children and youth who experience ignorance and prejudice about HIV may live in isolation, fearing rejection and judgment from others should they disclose their HIV status (35). They likely have few opportunities for the social support that may be offered by connection with similarly infected peers. They may "test" the reactions of others before disclosing by asking general questions or making comments about HIV/AIDS (36). Decisions not to disclose can lead to high-

risk sexual behavior and problems with adherence to medical treatment and medication regimens. Often the fear and expectations about stigma can exceed concerns about the disease itself.

The American Academy of Pediatrics has recommended that HIV-infected children be informed of their diagnosis (37). Most protocols suggest that the disclosure should be a dynamic process, involving multiple conversations that are tied to the child's cognitive development and deepen his or her understanding of the HIV infection (38). Although disclosure of other life-threatening illnesses, such as cancer, appears to alleviate anxiety, the social stigma associated with HIV infection may cause some children to experience periods of heightened distress.

Fear, shame, and guilt interfere with disclosure of an HIV diagnosis. Parents may avoid questions about their illness or that of the child due to their own guilt and worry about harming the child emotionally. Some worry about a loss of privacy, including unauthorized disclosure of protected health information (39). They may worry about disrupting a child's sense of normalcy and being like others in this context of illness accompanied by social approbation. In an attempt, albeit an ineffective one, some parents or guardians may make partial disclosures, providing information without naming HIV. A child may be told about having a different, less stigmatizing illness.

Permanency Planning and Transition to Adult Care

As those who were perinatally infected grow into adolescence and young adulthood, the focus on permanency planning during the early years of the epidemic has shifted toward transition to and engagement with adult medical care. In the 1980s and 1990s, permanency planning for children of HIV-infected parents was of paramount concern as HIV/AIDS became the leading cause of death for adults of child bearing age (40). Plans to ensure that the physical and emotional as well as custodial needs for HIV-affected children were at the forefront of concerns to reduce distress in children and improve their coping (37). The urgency of permanency planning has since waned, and in 2012 the American Academy of Pediatrics retired their policy statement regarding planning for children whose parents were dying of HIV/AIDS (41).

Given the longstanding relationships with providers, sometimes since infancy, there can be a great deal of anxiety about transitioning to the adult care system (38). Some fear the loss of their medical home (42). Youth may be ill prepared to take on responsibility for their own medical care, perhaps having little understanding of their HIV disease (HIV literacy) and knowledge of their medical history. Some providers in the adult HIV care setting lack knowledge and experience with this developmental transition or the unique challenges of a long-term survivor. Where pediatric clinics often provide an array of services beyond physicians specializing in pediatric HIV (e.g., social workers, case managers, incentives for medication adherence), adult

systems provide fewer ancillary services and provide less active assistance in managing complex medical needs.

NEUROLOGIC AND DEVELOPMENTAL EFFECTS FOR CHILDREN WITH HIV/AIDS

Neurologic, neuropsychological, and developmental manifestations of HIV disease can be the earliest and most devastating markers of infection in children. In fact, neurodevelopmental dysfunction was one symptom of HIV infection that brought children to the attention of a medical community that still saw HIV/AIDS as an adult disease in the early 1980s. Early studies indicated that between 40% and 90% of HIV-infected children had some degree of neurologic involvement (43). These studies, however, were generally conducted in cohorts of children with more advanced disease and before the widespread use of highly active antiretroviral treatment (HAART).

Although early, aggressive, and well-monitored treatment has dramatically reduced HIV/AIDS effects on the central nervous system (CNS), there remain aspects of CNS effects that warrant attention by mental health professionals monitoring and treating the child's psychological status, such as more subtle cognitive and behavioral difficulties that affect learning and social adjustment (44,45). Studies of the CNS as a possible reservoir for HIV and follow-up study of the long-term neurocognitive associations with childhood HIV/AIDS continue to explore the effects of the virus and compromised immune system on child development. Of note, HIV/AIDS in children can be associated with other adverse factors, such as poverty, family disruption, and other perinatal risk factors that also may affect child learning capacity and behavior (46).

An extensive history focusing on developmental milestones and a detailed neurologic examination are important in alerting the mental health clinician to the possibility of the neurodevelopmental and learning effects of HIV/AIDS. A neuropsychological assessment is warranted when there is any suggestion of developmental abnormalities or sign of neurologic disease, which is useful in establishing an initial baseline, monitoring subsequent alterations in cognitive processing secondary to CNS involvement, and devising appropriate developmental or educational interventions.

MEDICAL INTERVENTION FOR HIV INFECTION

The present drug treatment approach to HIV/AIDS referred to as HAART, includes starting treatment early and achieving maximal suppression of viral replication using a combination of at least three different antiretroviral medications. Fortunately, these

combination drug protocols have successfully reduced viral load to undetectable levels and preserved immune functioning in as many as one-half of the children who had access to the treatment and who adhered to the protocol (5). Of course, these successes have been documented in wealthy countries in which these expensive treatments are feasible, but less so in low resource countries where HIV/AIDS in children is most prevalent.

A major challenge posed by the advances in therapy of HIV disease has been the need to ensure that patients consistently are able to take all of their medicines. Unfortunately, there is a potential for the virus to develop resistance to antiretroviral medications, particularly when treatment and medication adherence are inconsistent, thereby providing a window for resistant viral strains to replicate, dominate, and increase viral load. In this era of multiple medications for HAART from which to choose, the choices become limited once viral resistance has developed. One study reported a linear association between self-reported adherence and level of HIV viral suppression. Patients taking fewer than 80% of their prescribed doses of antiretroviral medications had a significant increase in viral load measurements compared with those who took more of their medications. Despite this serious risk, adherence is not simple or easy for children and families, and poor adherence is strongly related to mental health (47,48). Treatment regimens often call for a large number of medications, taken at regular intervals each day. Some of the medications are available only as large capsules that are difficult to swallow; others have a particularly bad taste. Important interventions for the care of children with HIV/AIDS include support and strategies for children and families in taking medications on time and more easily.

Psychiatric Effects among Children and Adolescents

Psychiatric symptoms and disorders among HIV infected, affected, and at-risk youth occur at levels above those found in the general population. These include anxiety, depression, posttraumatic stress, and behavior problems (19,49–52). Infected youth contend with chronic, often life-threating illness, complex psychiatric symptoms, and environments marked adversity (51). One study indicated that youth diagnosed with one or more psychiatric disorders were more likely to be sexually active before adulthood, inconsistent in their medication compliance, and involved in alcohol or drug abuse (OR = 2.33) (52). In a study of HIV-infected Tanzanian adolescents, each year increase in age was associated with a 12% increase in depression. The likelihood of depression increased further when youth were female (62%), not attending school (65%), or experienced stigma (9%) (15). After controlling for the severity of mothers' symptoms, results from a 3-year longitudinal study indicated higher levels of internalizing and externalizing symptoms, as well as greater impairments in children's social competence among urban-dwelling, HIV-affected,

school-aged children (53). Between 52% and 74% of children who have been orphaned due to parental death from HIV/AIDS experience clinically significant internalizing and externalizing symptoms prior to and following their parent's death when compared to HIV-affected children whose parents remain living and to children of uninfected parents (54).

TRAUMATIC STRESS

Trauma and traumatic stress may serve as a risk factor for contracting HIV, for example, US studies suggest that up to 14.6% of HIV-positive adults have experienced sexual abuse, which in some instances may be the source of HIV infection (55,56). Other studies have suggested that HIV is one among many stressors, albeit a severe one, that can lead to distress and psychiatric symptoms. Stressors that might lead to similar clinical presentations may include multiple caregiver and family losses; responsibility to care for a dying parent; residential, educational, and economic instability; maltreatment; and exposure to violence. Factors that create risk for children contracting HIV (sexual risk taking and drug use in adolescence) (57,58) increase their risk for other negative outcomes. In a study of 1,258 orphaned and abandoned children in five LMICs (59), 98% had experienced at least one traumatic event in addition to the death of a parent due to HIV. Fifty-five percent experienced four or more trauma in addition to parental death. Their traumatic experiences were associated with more prevalent anxiety, conduct problems, and total symptomatology relative to children orphaned for other reasons and children who were not orphans.

Parents and Caregivers

The unpredictable course of HIV/AIDS, marked by multiple episodes of relapse and recovery and a chronic course of illness, may limit HIV-infected parents' ability to provide consistent and stable care and perpetuate a sense of anxiety among their children (51,60,61). In the instance of mother-to-child transmission, parents may contend with guilt at having transmitted the virus, distress and depression secondary to their own illness, and limitations in their capacity for consistent, responsive parenting. Caregiver illness severity, depression, and poor family cohesion, as well as changes in caregivers, have been associated with children's psychiatric status and psychosocial functioning (62,63). From 25% to 74% of adolescents residing with a parent diagnosed with HIV/AIDS consistently have reported high levels of parent–child conflict, academic failure, peer relationship problems, and delinquent behavior (64).

Resilience

Despite the ubiquity of psychiatric problems, many infected and affected youth are resilient and do not develop serious symptoms. Studies of child resilience in the face of HIV have pointed to several factors associated with resilience: positive coping, parent–child relationships, and communication; close parental monitoring; family functioning; and social and peer support (19,49). The complex interplay of resilience and psychiatric status was highlighted in a study of children following the death of an HIV-infected parent. Initially, children who had taken on a parental role during the illness had more distress, behavior problems, and substance abuse. Yet over time, they came to cope and engage social support more effectively and to abuse alcohol and tobacco less often relative to youth who had not taken on this role.

PSYCHOSOCIAL INTERVENTION FOR HIV/AIDS

As with a range of conditions, standards for prevention and psychiatric treatment for HIV infected, affected, and at-risk youth emphasize evidence-based interventions. Although specific criteria for designation as evidence based vary, an expectation of two or more randomized controlled trials (RCTs) showing clinical efficacy is widely accepted (65–68). The number of randomized trials for child and adolescent HIV interventions continues to increase although few are yet supported by a second RCT.

Prevention models typically have been based on psychoeducational and problem-solving approaches to sexual and other risk behaviors. They have demonstrated a range of positive outcomes in HICs and LMICs, including increased condom use, decreased high-risk sexual behavior, increased age at time of first intercourse, and increased discussion of sexual practices between parents and children (69). Secondary prevention and treatment studies have yielded outcomes that include changes in risk behavior, depression, behavior problems, and posttraumatic stress. The growing strength of evidence has not been accompanied by a significant increase in availability of evidence-based interventions.

PRIMARY PREVENTION

Primary (or universal) prevention programs focus on a population of youth rather than a subset selected on the basis of demographics or clinical presentation. Many interventions have demonstrated effectiveness with general populations and some in HIV-specific contexts (70,71). Programs have involved populations of students in a particular grade (i.e., 7th, 10th), including youth from racial and ethnic minorities and from countries other than the United States. Tenth graders in a large Bahamian city were randomized to a youth intervention with and without a parent supplement, as

well as to an attention control and a no intervention group (72). Eighteen months later, students in all four groups had improved in HIV/AIDS knowledge, condom use skills, self-efficacy about condom use, and self-reported rates of condom use; youth receiving both youth and parent components derived greater benefit. Native American middle schoolers completing a culturally adapted HIV prevention program had significantly higher HIV-related knowledge at 3-month follow-up relative to control, although effects had dissipated by 12 months. In an RCT involving 7th grade Latino adolescents in the United States, a culturally specific HIV prevention program with and without parent components yielded improvement in family functioning, although not in sexual risk behavior (73).

Kershaw et al. conducted an RCT of the empirically supported Centering Pregnancy program that has been shown to reduce preterm birth and increase medical treatment satisfaction with prenatal care. New mothers received Centering Pregnancy with and without the addition of three sessions focused on HIV prevention education and skills training (74). At 6 and 12 months' postpartum those receiving the HIV supplement used condoms more frequently. At 12 months, frequency of unprotected intercourse was lower, and mothers had more communication with their sexual partners about safe sex practices.

SECONDARY PREVENTION AND TREATMENT

Secondary prevention and treatment select intervention recipients based on risk criteria or clinical need (75–77). An increasingly strong empirical literature supports medium-to-large effects for prevention programs and EBTs for children and adolescents (67,78–80). Some of the interventions are designed for HIV populations; others have strong empirical support but have not been tested with HIV samples.

Project Teens and Adults Learning to Communicate, a well-researched, group-based, cognitive behavioral intervention for parents with HIV and their adolescent children, has been evaluated in two RCTs (81). In the first, the 24-session program addressed cognitive and emotional coping and postbereavement adjustment and transition. Two years following intervention the adolescents who received the intervention had less psychological distress, including depression, anxiety, and conduct problems. After 4 years, unwanted pregnancies were fewer, as were stressful family events (82). By 6 years, problem and conduct behaviors had increased in both conditions, albeit at a lesser rate in the treatment condition. Those who had received treatment were more likely to be employed or enrolled in school, have better problem-solving skills, and have positive future expectations, and were less likely to receive welfare benefits (83). Another extended follow-up revealed that grandchildren of the HIV-infected mothers had fewer internalizing and externalizing symptoms, higher scores of cognitive development, and better home environments relative to those in the control condition (84). Ten years later, a

second, well-designed RCT of a 16-session version did not replicate these positive outcomes, perhaps, although arguably, affected by changes in groups who were HIV infected during the decade between studies (85).

Other studies have yielded equivocal results. A 7-year follow-up from an open trial of an intervention for HIV-infected mothers revealed that maternal functioning exerted a direct effect on child self-concept, which in turn, affected child depression (86) rather than a direct relationship of maternal functioning with child depression. An RCT designed to reduce parenting stress among HIV-infected mothers did not result in differential benefits between intervention and control groups (87).

The focus of studies has shifted to LMICs and, in the process; the feasibility of adapting interventions developed in HICs to LMICs has become evident (6,88–90). South African HIV-infected mothers and their school-aged children were randomized to a 24-session group intervention or services as usual. Although attendance was problematic (54% attended fewer than 16 of the 24 sessions), mothers receiving the intervention reported improvements in their children's externalizing symptoms, communication, daily living skills, and socialization. No intervention benefits were detected for child internalizing symptoms, depression, or adaptive behavior, or for maternal functioning.

A well-validated US intervention was adapted, with feedback from community members and stakeholders, for families with 10- to 13-year-old, HIV-infected youth living in an LMIC. In contrast to the emphasis on verbal and written communication in the US version, the LMIC adaptation used a cartoon-based storyline to facilitate difficult conversations related to HIV. With a dearth of trained mental health professionals in LMICs, trained lay counselors served as interventionists and provided the intervention skillfully. Medication adherence improved among youth, and caregivers reported better communication with their children. Differences in emotional and behavior problems did not occur.

A 12-session, group-based adaptation of Trauma Focused Cognitive-Behavioral Therapy (TF-CBT) for traumatic grief (91) was delivered by rigorously trained lay counselors to HIV/AIDS orphans, ages 7 to 14, in an open trial (6). Children were notably symptomatic at baseline assessment. Three and 12 months following treatment, children self-reported significant improvement in grief (d = 1.36) and posttraumatic stress symptoms (d = 1.87); caregivers reported less traumatic stress among the children (d = 1.15).

CONCLUSIONS

HIV/AIDS continues to be a global health crisis that disproportionately affects youth, who represent the fasting growing group becoming infected. The overall number of new HIV infections has decreased, largely due to the greater availability of highly active antiretroviral treatment, although less so in LMICs. Earlier and effective

pharmacotherapies have dramatically reduced mother-to-child transmission, and contrary to expectations during the early years of HIV, youth who were infected perinatally are living into adolescence and adulthood. Treatment successes have been diminished, however, due to problems with medication adherence, resistance to antiretroviral treatment, and insufficient availability of medical care in LMICs. The number of infected adults of childbearing age continues to increase. Large numbers of children and adolescents are affected by parental illness and, in LMICs, orphaned. Youth who are infected with and affected by HIV experience significant psychiatric distress, including anxiety, depression, posttraumatic stress, and behavior problems, and engage in sexual and other behaviors that increase their risk for infection or infecting others (e.g., sex with multiple partners, inconsistent condom use, substance abuse).

Evidence-based prevention and mental health treatment have been effective in mitigating or reducing sexual risk behaviors and improving psychiatric symptoms for HIV infected and affected children and adolescents. The quality of evidence has improved with more RCTs in HICs and LMICs, although results have not been consistently positive. Interventions include those developed specifically for HIV populations and well-validated treatments that have been applied or adapted for HIV populations. Unfortunately, need for effective interventions far outstrips their availability.

Once effectiveness has been established, a next and rarely undertaken step is to study dissemination, implementation, and scale up so that best practices become readily available. Absent a systematic, comprehensive approach to training in evidence-based interventions, they are unlikely to become part of standard care (92). To change practice, researchers, trainers, and clinicians must forego traditional training methods that are ineffective (e.g., seminars) in favor of rigorous methods that assure intervention fidelity among learners, provide case-specific feedback, and offer guidance about barriers to practice change (93–95).

Although effectiveness research is a complex and sometimes daunting endeavor, limitations in emphasis and methods in the existing literature highlight critical areas for future research, including: (1) differentiating psychiatric symptoms that are specific to HIV/AIDS from those that are attributable to other risks and stressors (19,49–51,62), (2) adaptation and study of existing evidence-based interventions to HIV populations, (3) replication studies, (4) control groups consisting of active treatment comparisons, (5) well-validated assessment measures common across studies, (6) assessment of intervention fidelity, (7) duration and clinical significance of outcomes, and (8) better reported study methods and analyses (e.g., sample characteristics, statistical power).

Given the myriad psychosocial stressors encountered by HIV infected and affected children and adolescents, comprehensive and effective medical and mental health services remain crucial for management of the disease and associated psychiatric

symptoms. Access to care must be extended to children, adolescents, and families who have traditionally existed at the margins of the health care delivery system. Providers should draw upon the array of evidence-based prevention and treatment models for those conditions that are prevalent among infected and affected children, including depression, posttraumatic stress, and externalizing behaviors. To be maximally effective, psychiatric treatment must address children's well-being through a comprehensive strategy that addresses the medical and mental health needs of individual children, supports family functioning, and addresses transitions from pediatric to adult care.

CHAPTER 7.2.4 ■ EPILEPSY

KAIZAD MUNSHI, CATHERINE BROWNSTEIN, ALEXANDER ROTENBERG, GAUTAMI K. RAO, YANN B. PONCIN, AND JOSEPH GONZALEZ-HEYDRICH

Epilepsy, or recurrent seizures, is one of the more prevalent chronic disorders affecting children, and children and adolescents with epilepsy are at greater risk for psychiatric illness when compared to age-matched patients with other chronic illnesses. Psychiatric disorders are often undiagnosed and poorly managed in these children, despite parent perceptions that the emotional problems are among the more burdensome parts of the illness (1,2). The arrows of directionality go the other way as well: Children with ADHD and adults with major depressive disorder (MDD) are at increased risk for developing epilepsy (3,4). Increasingly, the genetic overlaps between epilepsy and major psychiatric disorders are being recognized. Many identified genetic mutations pleiotropically manifest as epilepsy, autism, psychosis (5–7), and ADHD while each of these clinical entities show great deal of genetic heterogeneity (5). Moreover, some psychiatric medications can worsen seizures, while certain anticonvulsants are useful as treatments for psychiatric disorders. Thus, the study of the pathophysiology of epilepsy may shed light on that of the psychiatric disorders with which it is associated, and vice versa. Child psychiatrists have important contributions to make to the recognition, treatment, and research into the psychiatric repercussions of epilepsy in children. This chapter will provide an overview of epilepsy, its epidemiology, management, and prognosis. Finally, it will also focus on psychiatric disorders associated with epilepsy and offer guiding principles for psychopharmacological management.

DEFINITIONS

A seizure results from a disturbance in the brain's electrical system in the form of an abnormal, hypersynchronous firing of cortical neurons. Its manifestations may be behavioral or sensory and these may be obvious or subtle. An individual seizure may have a variety of causes, such as fever in a young child, hypoxia, hypoglycemia, or infection. Epilepsy is the condition of recurrent seizures in absence of provoking stimuli, or a strong predisposition to recurrent unprovoked seizures as may happen in many genetic syndromes or other diseases of the central nervous system (CNS) (8,9). Nonepileptic seizures (NES), under which psychogenic seizures are classified, may appear similar to epileptic seizures but are not caused by hypersynchronous electrical disruptions in the brain. The time leading up to a seizure, the seizure itself, and the time immediately after a seizure are respectively referred to as the preictal, ictal, and postictal periods. The time in between seizures is called the interictal period. While seizures are the defining and most dramatic manifestation of epilepsy,

they are episodic, whereas the brain dysfunction underlying them continues during the interictal periods, as can the associated psychosocial impact. Thus seizures themselves are rarely what is most impairing for children with epilepsy (Table 7.2.4.1).

EPIDEMIOLOGY

While epilepsy is the fourth most common neurologic problem overall (10), it is the most common neurologic condition in the pediatric population (11,12). Among youth in the United States in 2007, it had an estimated lifetime prevalence of 1% and the prevalence of current epilepsy (i.e., point prevalence) was 0.6%, corresponding to 450,000 cases between 0 and 17 years of age. In the United States, in any given year, 1 in 200 children under 15 will have epilepsy (13), or about 326,000 children (10). Annually, recurrent unprovoked seizures, or epilepsy, will develop in up to 7 in 10,000 children under the age of 15 years (13), which represents the annual incidence. Across developed countries, the annual incidence is similar (14,15). In US surveys, the incidence of epilepsy is greatest among the very young and the elderly and is generally higher in males, after the age of 5 years (16). Whether the incidence of epilepsy is higher in African Americans or populations with lower socioeconomic status, as reported by some (17,18), is contradicted by others (19,20). Across age groups, in two-thirds of patients the etiology is unknown (16). Populations at special risk for epilepsy are those with a single unprovoked seizure, autism (21), intellectual disability, cerebral palsy (22), and children of parents with epilepsy (23).

TABLE 7.2.4.1

COMMON CAUSES OF SEIZURES

High fever[a]
Systemic or CNS infection (meningitis, encephalitis, etc.)
Hyperthermia (exogenous)
Congenital disorders of brain development[a]
Perinatal hypoxic/ischemic injury[a]
Tuberous sclerosis
Phenylketonuria
Head trauma[a]
Intracranial hemorrhage
Neoplasm
Metabolic derangements (hypoglycemia, hyponatremia, etc.)
Anoxia
Cardiac disorders
Intoxication (medications, recreational drugs, environmental toxins)
Autoimmune disorders
Lupus, CNS vasculitis, etc.

[a]Most common in children.

PROGNOSIS

Approximately 70% of people with epilepsy will go into remission, defined as 5 or more seizure-free years, whether on or off medication (24). Prognosis will vary according to age and seizure type, with a better prognosis for childhood-onset epilepsy without neurologic or developmental disabilities. A decade's longitudinal follow-up study found that more than one-third of patients with childhood-onset epilepsy with more than 5 years of remission who then stopped their medications relapsed within the next 5 years (25). Approximately 10% of children newly diagnosed with epilepsy will go on to have intractable epilepsy (26). The course and prognosis for the most common psychiatric comorbidities of epilepsy have not been well studied. However, it is clear that for many patients these continue long after seizures have stopped.

INTERTWINING OF EPILEPSY AND PSYCHIATRY: PAST AND PRESENT

The first written records of epilepsy date back to 4000 BC (27). Hippocrates also wrote about epilepsy in 400 BC, describing it as having a natural cause, like other medical conditions, rather than being a divine curse as previously thought. He noted also the association with depression and wrote that *"melancholics ordinarily become epileptics, and epileptics, melancholics: what determines the preference is the direction the malady takes; if it bears upon the body, epilepsy, if upon the intelligence, melancholy"* (28). This coarse link between epilepsy and psychiatric disease continued into the modern era. In mid-19th century England, epilepsy was considered a form of insanity (29). In the late 19th and early 20th centuries, with the advent of neurology as a specialty and the successful use of bromide and barbiturates to suppress seizures, epilepsy became increasingly viewed as a brain disorder, and its social stigma attenuated. However, into the 21st century, large segments of the public continue to have highly negative perceptions of epilepsy (30).

Although epilepsy in modern medicine is not viewed as a simple causal explanation for severe psychiatric illness, the overlap between epilepsy and psychiatry is being increasingly recognized. Seizures can produce alterations in consciousness that can mimic psychiatric symptoms in the ictal and peri-ictal periods, particularly when seizures arise from the temporal lobes (31). There is also a high prevalence of psychiatric comorbidity in the interictal period. Clearly, the presence of epilepsy has neuropsychiatric and psychological associations, if not sequelae. These problems can be conceptualized along two domains: (1) The brain dysfunction causing seizures, the seizures themselves, and adverse effects (AEs) of antiepileptic drugs (AEDs), and their potential contribution to psychiatric pathology,

through common physiologic mechanisms, and (2) the psychosocial and psychological consequences of epilepsy or its treatment, irrespective of any biologic overlap.

Regardless of etiology, the psychiatric considerations include the child's concerns about self-image and self-esteem, which can be related to the seizure disorder itself or side effects of drug treatment; intrapsychic issues related to temperament and coping skills; psychosocial issues, such as withdrawal and social isolation in contrast to affiliation; the cognitive impact of seizures or their treatment, including decrements in IQ or other neuropsychological changes; the impact of the disorder or its treatment on daily living (32); and the developmental impact of any or all of these on the individual child in maintaining his or her developmental trajectory.

Learning to live with this chronic, at times severe, disorder while remaining psychiatrically healthy can be a challenge for some children. Child psychiatrists can play an active role in recognizing and treating these psychiatric repercussions or in helping to educate others to do so. With the aim of better helping children who have epilepsy and comorbid psychiatric disorders, it is useful to have a familiarity with the fundamental diagnostic, classification, and treatment considerations in epilepsy. This is reviewed in the following sections, before turning back to psychiatric aspects in more detail.

DIAGNOSIS AND EVALUATION

Most evaluations begin, naturally, with the clinical suspicion that a child is having seizures. These can range from the dramatic, such as tonic–clonic convulsions, to the subtle, such as the brief staring spells of absence seizures. Other common presentations include paroxysmal sensations, repetitive movements, automatic behaviors, or altered consciousness. Most seizures are brief, lasting from a few seconds to several minutes. Afterward, depending on the type of seizure, a person may have a headache, confusion, fatigue, limb weakness, or feel nothing at all. Like all diagnostic evaluations, one begins with a detailed clinical history and a physical (including neurologic) examination. The clinical history is the single most important modality in making a diagnosis, as frequently, neurologic examination and diagnostic testing, including electroencephalogram (EEG)—which may not capture definitive interictal clues of vulnerability to seizure—will not yield any findings. Since the patient himself may have a poor recollection of the event, collateral information is essential. Generally, one wants to know at minimum the time and speed of onset; the presence of abnormal movements; whether bladder control was maintained; whether the patient bit his lips or tongue; how long the episode lasted; and how long it took for the patient to recover after the episode. Details about eye, face, and limb movements are very helpful in the epilepsy history as the lateralization of these can indicate the hemisphere or lobe of seizure origin. The patient can be asked directly

how he or she felt after the event and whether or not he or she had any premonitions of the event; these can include aural, visual, tactile, or olfactory sensations, among others. The clinical history and examination will help determine the additional workup needed. The workup almost always includes an EEG as it is among the best predictors of seizure recurrence, unless the examination is suggestive of obvious triggering pathology, such as a high fever in an infant or a headache, vomiting, and focal neurologic findings in a teenager, which indicate the need for urgent neuroimaging and other diagnostics.

GENETICS

Our knowledge of the genetics of the epilepsies has grown exponentially over the past two decades, resulting in a shift in the patient diagnostic journey. The advent of next generation sequencing (NGS), including whole-exome and whole-genome sequencing has improved the rate of detecting etiologically important mutations. The exome is the 1% of the genome that contains the coding region. Therefore, whole-exome sequencing has become the dominant method for defining human genetic diseases as it is powerful as well as economical (33). The advent of more intuitive analysis tools is making NGS more accessible for screening and diagnosing patients. Sequencing studies have defined rare, potentially deleterious mutations within the coding regions of candidate genes for epilepsy (34). A subset can be seen in Table 7.2.4.2.

Other genetic tests that are used to diagnose epilepsy include chromosomal microarray analysis (CMAs) and targeted genetic panels. CMAs evaluate copy number variations. These are duplications or deletions of stretches of a chromosome and typically engulf many genes. CMAs are particularly fruitful when epilepsy occurs alongside developmental delay, dysmorphisms, or intellectual disability. Targeted gene panels are focused on analyzing, in greater depth, a selected set of genes or gene regions that are implicated in a disease. They typically involve NGS, which allows for massively parallel sequencing (many more samples sequenced at once), lowering cost. Another test used in certain situations is genome-wide methylation analysis, which provides a comprehensive view of methylation patterns across the genome and is useful for diagnosing disorders including Prader–Willi and Angelman. The use of more advanced testing including deep sequencing and single-cell sequencing is also being increasingly utilized.

TABLE 7.2.4.2

SELECTED GENETICALLY LINKED EPILEPSY SYNDROMES

Syndrome	Gene Defect
Doose syndrome	SLC6A1, likely others
Epileptic encephalopathies	SCN1A, DNM1, GABBR2, FASN, PCDH19, RYR3, CDKL5, likely others

Angelman syndrome	Maternal deletion or mutation of 15q11–q13 (68%) Uniparental disomy of 15q11–q13 (7%) Methylation defect of 15q11–q13 (imprinting error) (2–4%) UBE3 mutation or deletion (12%) (Inheritance pattern varies with defect)
Rett syndrome	*MECP2*

TABLE 7.2.4.3

TYPICAL FREQUENCIES AND AMPLITUDES OF EEG RHYTHMS

Rhythm	Typical Frequency (Hz)	Typical Amplitude (IV)
Alpha	8–13	20–200
Beta	13–30	5–10
Delta	1–5	20–200
Theta	4–8	10

THE ELECTROENCEPHALOGRAM: BASIC TERMINOLOGY

In the late 19th and early 20th centuries, the EEG was an experimental tool applied to the scalp of animals to examine electrical currents in the brain. In 1929, German psychiatrist Hans Berger published a report on his experiments using it to record the fluctuating electrical potentials of the human cortex (35). He identified the posterior dominant rhythm and called it alpha. Later on, rhythms in other frequency ranges were identified and called beta, gamma, delta, and theta (see Table 7.2.4.3). Soon, the EEG became the prime tool in diagnosing seizures and it remains decades later, now along with neuroimaging, a key instrument in diagnosing epilepsy.

To understand various epilepsy syndromes, one must also be familiar with the basic terminology used to describe EEG tracings. EEGs are traditionally acquired using the 10–20 international electrode placement system, in which electrodes are placed with even spacing over the scalp (36).

The EEG typically starts in wakefulness with the technician asking the patient to close his or her eyes, or in the case of children, placing a hand over the child's eyes. This is done to bring out the occipital alpha rhythm, which is the predominant rhythm of the resting cortex (as is with the occipital cortex when eyes are closed) during wakefulness. Opening the eyes will usually attenuate the alpha occipital alpha rhythm.

As the patient transitions from wakefulness to drowsiness, the background rhythms slow, with theta and delta frequencies becoming most prominent. Paroxysmal EEG activity specific for sleep, such as sleep spindles, appear in this stage and distinguish deeper sleep stages from drowsiness and early sleep.

During the acquisition of the EEG, certain maneuvers are attempted to provoke seizures, including hyperventilation and photic stimulation. The response of the brain

to these maneuvers helps the observer to determine if the patient is within the normal range, or may be encephalopathic. For example, an encephalopathic child will have prolonged delta after hyperventilation, and may have a slower-than-normal background at baseline. A patient with absence epilepsy can have an otherwise normal background, but with the onset of hyperventilation, a 3-Hz spike and wave pattern appears along with behavioral arrest. The EEG is also useful because certain epilepsy syndromes have typical and at times, diagnostic EEG patterns.

Several elemental EEG waveforms are presented in Table 7.2.4.3. In most children, an alpha rhythm with an 8-Hz frequency is reached by the age of 3 years.

EPILEPSY: CLASSIFICATION

The 1989 International League Against Epilepsy (ILAE) classification scheme for epilepsy syndromes divided epilepsies into focal- or localization-related syndromes versus generalized ones, and according to etiology. However, due to recent advances in human genomic technology, neuroimaging, and molecular biology (37,38), that scheme is no longer considered adequate. According to the 2010 ILAE proposal, the etiologic terms "idiopathic," "symptomatic," "provoked," and "cryptogenic" that were previously used to describe epilepsy are to be replaced by "genetic," "structural-metabolic," and "unknown" (37,38).

A seizure's manifestations depend on where it starts and where it spreads. Broadly, mechanisms of seizure onset can be classified as generalized (with onset in both hemispheres) or focal. Recalling that the definition of epilepsy is recurrent seizures that occur spontaneously in the absence of provoking stimuli, an isolated seizure is not considered to be epilepsy. An epilepsy syndrome has distinguishing patterns of signs, symptoms, and history. These include the seizure type, whether it starts at an identifiable place or focus in the brain (these can be termed "focal," "partial," or "localization-related" seizures); or whether it has a generalized onset. Partial/focal seizures are further classified according to whether they cause alterations in consciousness (complex partial) or consciousness remains intact (simple partial seizure), and whether they progress to generalized convulsions (with secondary generalization) or not. The definition of an epilepsy syndrome also commonly includes the age of onset, family history, physical examination, EEG findings during and between seizures, etiology, imaging findings, and prognosis.

Common causes of seizures in the first year of life are perinatal complications such as stroke and diffuse hypoxic/ischemic injury, febrile seizures, infections, and metabolic disorders. In adolescents and young adults, common causes are trauma, congenital abnormalities, tumors, and CNS infections. A concern germane to psychiatrists is differentiating paroxysmal nonepileptic events and NES from true epilepsy. Further complicating matters, patients with NES may also have concomitant epileptic seizures. Video EEG monitoring is the ideal modality to differentiate these

events.

In the first year of life, generalized seizures are the most common type. The incidence then declines and remains constant throughout childhood and adulthood. Thereafter, partial seizures are the most common type in childhood (39), and the incidence is constant until after age 65, when a precipitous increase occurs attributable to cerebrovascular disease. Absence (what was previously referred to as *petit mal*) seizures, considered in the differential diagnosis of ADHD, rarely occur in the first year, peak from the ages of 5 to 10, and then decline, being quite rare by the age of 30. The incidence of various epilepsy syndromes in newly diagnosed children is described in Table 7.2.4.4, while clinical features and treatment of the various epilepsy syndromes commonly found in children is described in Table 7.2.4.5.

TABLE 7.2.4.4

RELATIVE FREQUENCY OF EPILEPSY SYNDROMES IN A COMMUNITY SAMPLE OF CHILDREN AGED 0 TO 15 YEARS (*N* = 613)

Epilepsy Syndrome	Relative Frequency (%)
Localization-related	58.6
Symptomatic	31.8
Cryptogenic	16.8
Idiopathic	10
Generalized	29
Primary generalized	20.6
Cryptogenic/symptomatic	7
Other syndromes	12.4

Adapted from Berg AT, Shinnar S, Levy SR, Testa FM: Newly diagnosed epilepsy in children: presentation at diagnosis. Epilepsia 40(4):445–452, 1999.

TABLE 7.2.4.5

SELECTED CHILDHOOD EPILEPSY SYNDROMES AND TREATMENTS

Epilepsy Syndromes	Common Clinical Features	Common Treatments
Benign rolandic epilepsy with centrotemporal spikes (BRECTS)	Mouth twitching, drooling, variably GTC; nocturnal predisposition	If indicated (often untreated given favorable prognosis), levetiracetam, oxcarbazepine
Temporal lobe epilepsy	Gastric or olfactory aura, confusion, automatisms, often followed by GTC	Levetiracetam, oxcarbazepine, lamotrigine; zonisamide also helpful
Frontal lobe epilepsy	Hypermotor activity (bicycling, etc.) with change in behavior; often at night; variably with evolution to GTC	Levetiracetam, oxcarbazepine, lamotrigine; zonisamide also helpful
Juvenile myoclonic epilepsy (JME)	Brief myoclonic jerks, GTC	Valproate, lamotrigine, levetiracetam
Childhood absence epilepsy	Staring and brief multiple episodes of behavioral arrest	Ethosuximide (drug of choice), valproate, lamotrigine
Juvenile absence	Myoclonic jerks and staring spells with	Valproate, ethosuximide,

epilepsy	older age of onset	lamotrigine, levetiracetam, topiramate
Epilepsy with GTC	GTC that can occur upon awakening or at any time of day with no partial onset	Levetiracetam, valproate, lacosamide, perampanel

GTC, generalized tonic–clonic seizures.

BEHAVIORS THAT MIMIC EPILEPSY

Children often have behaviors that are paroxysmal and may be mistaken for seizures. In most cases, these events are easily defined and there is no treatment needed. There are some instances, however, when the only way to differentiate these events from true seizures is to use video EEG to confirm an EEG correlate. To ascertain a true seizure, determining the duration of the event, observing the presence of a postictal state, and obtaining a history to uncover any provocative stressors are all useful.

TABLE 7.2.4.6

BEHAVIORS THAT CAN BE MISTAKEN FOR SEIZURE ACTIVITY

Behavior of Psychiatric or Undefined Origin	Clinical Manifestations
Nonepileptic seizure	May appear very much like a true seizure, but there is no epileptiform activity on EEG. Duration greater than 10 min, the lack of a postictal state, and motor movements incongruent with seizure activity are clues.
Breath-holding	Crying followed by cessation of breathing. Within seconds, cyanosis occurs, followed by loss of consciousness and falling. Quick return to consciousness. No neurologic damage. Triggered by fear, frustration, or minor injury.
Staring	May need to rule out epilepsy, depending on clinical presentation.
Cyclic vomiting	Repeated, spontaneous vomiting lasting days, followed by asymptomatic periods. May have an EEG correlate.
Stereotyped movements	Tics or other stereotypes
Violent attacks	Violence associated with epilepsy is nondirected thrashing. If violence is organized this does not suggest epilepsy.
Shuddering	Shakes and shudders. No loss of consciousness. Lasts seconds.
Jitteriness	Jittering movements in infants. Stopped by holding down the arms.
Head drops	Can be mistaken for infantile spasms, but no EEG correlate.
Behavior Associated with Defined Syndromes	
Syncope	Variably followed by seizure (i.e., convulsive syncope)
Sandifer spasms in children with gastroesophageal reflux	Intermittent contractions of the neck with flexion and syncope.
Chiari malformations	Syncope from increased intracranial pressure. Torticollis, ataxia, opisthotonus, nystagmus.
Cardiac conditions	Lightheadedness, palpitations, pallor. May need EEG with EKG strip running to clarify etiology.

Cataplexy (e.g., of narcolepsy)	Atonia; partial or full loss of tone
Paroxysmal movement disorders resultant from channelopathies	Hard to differentiate at times, but no loss of consciousness.
Episodic ataxia types I and II	Brief attacks of cerebellar ataxia. Type 2 also involves eye movement difficulties.
Paroxysmal kinesigenic dyskinesia	Choreoathetosis or dystonia lasting seconds to minutes triggered by volitional movements such as getting up from chair or out of car.
Paroxysmal exercise-induced dyskinesia	Dystonia occurs 10–15 min after starting exercise.
Benign paroxysmal upgaze of childhood	Spells, lasting hours or days, of intermittent upgaze deviation associated with ataxia; language delay is often present.
Benign paroxysmal torticollis	Starts in infancy with attacks of torticollis lasting minutes or hours.

Behavioral events that may appear epileptiform were examined by Kotagal et al. in a retrospective study looking at 134 children and adolescents admitted to their pediatric epilepsy unit. They found that in children less than 5 years, the common diagnoses were parasomnias and sleep jerks. In the older age group, NES were common (40).

Behaviors that can raise the concern for epilepsy but are not epileptiform in etiology are outlined in Table 7.2.4.6.

NONEPILEPTIC SEIZURES IN CHILDREN

NES can be classified as physiologic or psychogenic. Physiologic NES are events that resemble seizures but are not caused by epileptiform discharges; these include, for example, syncopal episodes or hypoglycemia. Psychogenic NES (PNES) refer to behaviors that may resemble seizure activity, but which also are not epileptiform, and are rooted in a psychological etiology. In DSM-5, if they are volitional, NES might be classified as factitious disorder with predominantly psychological signs and symptoms or as malingering if secondary gain is a motive. If the NES are not volitional, conversion disorder with seizures or convulsions is the appropriate diagnosis. PNES are well documented in adult populations, with a prevalence of 2 to 33 per 100,000 (41). In children, NES can be more difficult to delineate from epilepsy as they are not as common. Moreover, children diagnosed with PNES also often carry a diagnosis of EEG-confirmed epilepsy. For example, one study of children with intractable seizures found that one-fifth had NES, and three-quarters of these children also had documented epileptic seizures (42). Kotagal et al. found that

15% of all patients monitored on their pediatric epilepsy unit had PNES; of these, close to half also had epilepsy (40).

The presence of NES in children is attributable to a variety of precipitants, most of which have some identifiable psychological or psychosocial component. In adults, they are frequently attributed to dissociative phenomena (43), posttraumatic stress disorder (44), and mood disorders. In one study designed to study the psychiatric features of children with NES, severe environmental stress and major mood disorders were the most common findings (45). The most common environmental stressor involved the family, including parental divorce, parental discord, or the death of a close family member. Sexual abuse was the second most common environmental stressor, occurring in 32% of children. Separation anxiety with school refusal was found in 24% of the children. Bhatia and Sapra found that school phobias and fear of examinations were the most common precipitating factors (46). Some investigators have found that a family history of epilepsy is commonly found in children with NES (47).

What does PNES look like? Many patients mimic their own seizures (48). Lancman et al. found unresponsiveness with generalized violent and uncoordinated movements or generalized trembling to be the most common manifestations (47). Others have found that tremors, intermittent stiffening, out-of-phase hand movements, and kicking and thrashing of the legs are most common, especially among adolescents; younger children often present less dramatically with staring or closing of the eyes and no responsiveness (49).

Diagnosing NES can be difficult. If a typical nonepileptic event is captured on video without an EEG correlate, there is a greater likelihood that the event is nonepileptic. However, frontal lobe seizures occasionally present without an EEG correlate. Hence, clinical observation is crucial. Generally, an event that has a duration of more than 10 minutes, that does not have a postictal state, and in which the movements are neuroanatomically incongruent with a seizure, is unlikely to be epileptic. Early psychiatric intervention is warranted to address these behaviors and prevent them from becoming more entrenched (50).

INTELLECTUAL DISABILITY AND EPILEPSY

Epilepsy is a common comorbidity in children with intellectual disability, with a direct correlation between the severity of intellectual compromise and the severity of chronic epilepsy. The prevalence of intellectual disability is about 1% of the general population (51), but epilepsy is found in approximately 20% to 40% of children with intellectual disability (52). In addition, about 40% of children with epilepsy have intellectual disability. The age at which epilepsy presents is related to the etiology of the intellectual disability.

Differentiating seizures from paroxysmal behaviors is at times difficult in children

with intellectual disability as this population has more frequent repetitive and stereotyped movements and behaviors than the general population. Several such nonepileptic entities include self-stimulation, hyperventilation, Sandifer syndrome, spasticity, clonus, dystonic posturing, and choreoathetosis (53). A study by Donat and Wright examined the most common types of behavior in a sample of 31 girls with intellectual disability. They found 23% had behavioral staring, 40% had abnormal eye movements, and 42% had tonic posturing (54).

Several studies have investigated the age at which seizures present in intellectual disability. One study of 98 children found that the average age of the first seizure was 1.3 years, with an earlier onset in children with severe intellectual disability and a later onset for patients with mild intellectual disability (2). Another study of 151 children with intellectual disability found that 69% had epilepsy by the age of 3 years, without difference between severe and mild intellectual disabilities for onset before or after the age of 3 years. Focal seizures predominated, with 72% of the children having these and 28% having generalized seizures. In this population, as in most studies, a prenatal cause for epilepsy was found in more than 40% of the intellectually disabled children (55). When severe epilepsies occur in infancy, they profoundly impact neuropsychological development (56). They are also usually quite difficult to control with AEDs, with many patients undergoing multiple AED trials before seizure control is improved.

Several epilepsy syndromes can result in significant intellectual disability, including infantile spasms, Lennox–Gastaut syndrome (LGS), and the epileptic encephalopathies. Many genes, including DNM1, GABBR2, FASN, and RYR3 are thought to be involved in these syndromes (57). Infantile spasms, or West syndrome, can be catastrophic. Some patients with infantile spasms will have an MRI lesion, such as cortical dysplasia, hemimegalencephaly, arteriovenous malformation (AVM), stroke, or other lesions. Patients present as neonates with extensor or flexor spasms, or a combination of both. They typically have multiple seizures daily, at times causing profound lethargy. Early diagnosis and treatment are crucial, and carry a more favorable long-term prognosis.

LGS is commonly known as a mixture of seizure types, including tonic, atonic, myoclonic, atypical absence, and generalized tonic–clonic seizures. Patients with LGS are universally intellectually compromised. The majority of children have onset between 3 and 5 years. Most cases have an underlying brain abnormality and are therefore classified as symptomatic. The intracranial pathologies associated with LGS include (but are not limited to) focal cortical dysplasias, diffuse subcortical heterotopias, and the cerebrovascular malformations of Sturge–Weber syndrome. Seizures in LGS occur multiple times daily, especially during sleep. At times, one seizure type predominates over others. In general, tonic seizures are the most common, and can be brief and safe. They may, however, lead to falls and a requirement for patients is to wear a protective helmet. Atypical absence seizures are

the second most common type of spell in Lennox–Gastaut, and are associated with some loss of muscle tone, or jerks. Myoclonic jerks are less common. Approximately 50% to 75% of LGS patients will experience nonconvulsive status epilepticus. The intellectual disability in Lennox–Gastaut is severe in most cases, but on occasion, further decline may be halted by controlling the seizures, since the seizures themselves seem to play a role in the cognitive deterioration. Successful treatment with complete seizure control is rare.

Epileptic encephalopathies are conditions in which the epileptiform abnormalities are thought to contribute to progressive cerebral deterioration, which impacts cognition and functioning. These are often associated with nearly continuous spike and wave discharges on EEG, leading to an alteration in consciousness.

Landau–Kleffner syndrome (LKS), also called acquired epileptiform aphasia, involves progressive neuropsychological impairment linked to the appearance of rhythmic EEG activity. Landau and Kleffner first described the correlation between language loss, in previously normally developing children, and paroxysmal EEG discharges in the speech centers (58). Mutations and disruptions (such as translocations) in the GRIN2A gene result in LKS (59,60). LKS is characterized by acquired aphasia and EEG findings that show bilateral, independent temporal spikes that are activated by early sleep. Secondary symptoms include behavioral and psychomotor disturbances. Boys are more affected than girls, with a 2:1 ratio. Children usually present between 3 and 9 years of age. Word deafness is a first sign; the child does not respond to commands from parents. Children with LKS are often referred for audiograms, which are normal. This initial symptom can develop into complete unresponsiveness and impaired communication. The child speaks in a brief, telegraphic manner, and communication may be limited to gestures. In an older child, reading and writing skills can be lost. LKS can also be mistaken for autism. Several important differences are present. Children with autism have language regression before the age of 3, whereas most children in LKS have regression between the ages of 5 and 7 (61). Children with LKS also retain their social skills and do not generally have stereotyped behaviors.

ANTIEPILEPTIC DRUGS: GENERAL CONSIDERATIONS

Patients are rarely started on an AED after a single seizure. Rather, AEDs are started if the seizure recurs or if there are compelling risk factors for recurrence. AED choice depends on evidence of efficacy for that seizure type, AE profile, interactions with other medications, and cost. Treatment is started with a single AED. If that AED is not effective, a second AED is chosen. A drug with a different mechanism of action and lack of drug–drug interaction with the first AED is preferred. The first AED is maintained until the second AED is at a therapeutic dose. Then if seizures are controlled, an attempt to taper off the first one is made. Monotherapy is preferred but

some patients will require more than one AED to control their seizures. Use of multiple AEDs simultaneously is associated with a greater likelihood of drug side effects.

The use of animal models and patient-derived induced pluripotent stem cells for functional analysis of genetic mutations has been key in understanding the pathophysiology and mechanisms of many of the epilepsies. However, the pharmacogenomics of antiepileptics is still underdeveloped—screening medications using the patient's own stem cells may, until recently, have sounded unconceivable, but may soon be possible.

Neuropsychiatric Effects of Antiepileptic Drugs

AEDs are of particular interest to psychiatry for three reasons: (1) many have cognitive and behavioral AEs; (2) many have desirable psychotropic effects such as mood stabilization and anxiolysis; and (3) both these sets of effects could provide clues into the pathophysiology of psychiatric disorders.

A number of studies have investigated the cognitive and behavioral side effects of AEDs over the last 40 years. However, there are fewer studies examining the specific side effects of AEDs in children. As a group, AEDs are thought to affect attention, vigilance, and psychomotor speed (62). Attempts to study these effects have been hampered by the difficulties of designing studies in a population with neurologic and developmental heterogeneity. Lack of consensus on how to test for AED effects also limits the power to detect effects, and to generalize from findings, and to compare across studies. The field continues to struggle to develop consistent study designs, testing paradigms, and ways of controlling for confounding variables (63,64). The effect of AEDs on cognition is difficult to disentangle from the effects of seizures and changes in seizure frequency and severity. Importantly, many of the studies on new AEDs are funded by their manufacturers to satisfy FDA requirements for approval. In these studies, efficacy in attenuating seizures is the primary outcome. Measurement of effects on cognition or behavior has received much less scientific attention in these trials. Adequate studies are also lacking that relate potential cognitive and behavioral side effects of AEDs to schooling and social adjustment (65). The impact of AEDs on the developing brain is unclear. While decreasing seizures is expected to have a beneficial effect, some studies have raised concerns. For example, in one study of the developing rat brain, some AEDs have been found to trigger neuronal apoptosis (66).

Several representative studies examine the effects of AEDs as a group on cognition. Williams et al. (67) administered neuropsychological testing to 32 children with newly diagnosed epilepsy, prior to and after initiation of medication monotherapy. They compared this group to a chronic condition comparator group of diabetic children. They found no significant difference between groups on measures

of attention, immediate memory, delayed memory, complex motor speed, or behavior problems. Likewise, Mandelbaum and Burack (68) also followed children prospectively and found no cognitive declines directly attributable to AED treatment. The relatively small sample size in both of these studies, however, limits their power to detect anything but large effects. In another study looking at subjective impressions, children and parents differed in their reports of cognitive side effects. Children reported no change in symptoms before and after AED discontinuation, whereas parents found their children to be more alert and active off the AEDs (69).

Despite the lack of conclusive data, it is helpful to examine what is known about the cognitive and behavioral effects of AEDs as a group, and of some individual AEDs that are commonly used in pediatric neurology. A more complete listing of AEDs can be found in Table 7.2.4.7.

With a few notable exceptions such as lamotrigine and felbamate, many AEDs are sedating and their adverse behavioral profile relates to their capacity to induce somnolence and to slow mentation. However, these are not universal and are often dose related. Mitigation and relief of such symptoms can be accomplished by slow titration and use of minimally effective dose. Another common trend is for newer AEDs to produce fewer AEs than the older ones but this is not consistent across all types of AEs. Finally, several concerning reports indicating increased risk of suicidal ideation and suicidal attempts in patients taking AEDs have led the FDA to consider boxed warnings about increased risk of suicidality for essentially all approved AEDs (70). This however, remains controversial, and a recent study found that the association between suicide and epilepsy that exists even before epilepsy manifests, suggesting a common underlying etiology rather than the effects of AEDs (71).

Phenobarbital is among the oldest anticonvulsants and used to treat largely neonatal seizures. In older patients, it is still at times used to manage focal seizures and generalized seizures, except absence seizures, but rarely as a first choice AED. Phenobarbital can have significant AEs on cognition, mood, and behavior. It can also cause hyperactivity, irritability, and depression. Studies have raised the concern that phenobarbital is associated with decreases in IQ, whereas others have not supported this finding (72,73). Cognitive deficits may be reversible with treatment discontinuation, but some published reports indicate that deficits may persist over several years (74). This raises the concern that there exist cumulative impairments that are not completely reversible with extended periods of treatment with some AEDs. Notably, barbiturates (including phenobarbital) are most likely to cause depression and suicidal ideation in patients with a family or personal history of affective disorder (75). Gradual conversion to a nonbarbiturate antiepileptic medication is thus advised for depressed, irritable, or aggressive patients with epilepsy who are on long-term barbiturate therapy.

Phenytoin is effective in treatment of focal and generalized tonic–clonic seizures.

It is known to cause a decrease in mental speed and concentration, even at therapeutic ranges in adults (76). In children, there is less literature, but a dose-related slowing in mentation has been observed. It can also cause gingival hyperplasia, hirsutism, and coarsening of facial features. Phenytoin's efficacy varies by patient, partly due to genetic variations in the gene-encoding cytochrome P450 (CYP)2C9 (CYP2C9), which metabolizes the drug (77). Furthermore, the variant allele HLA-B*15:02, encoding human leukocyte antigen, is associated with an increased risk of Stevens–Johnson syndrome and toxic epidermal necrolysis in response to phenytoin treatment (78). Certain ethnicities are more prone to Stevens–Johnson syndrome (78). The Clinical Pharmacogenetics Implementation Consortium (CPIC) guidelines provide information for the interpretation of HLA-B and/or CYP2C9 genotype tests so that the results can guide dosing and/or use of phenytoin.

Carbamazepine had been one of the more commonly used medications in pediatric epilepsy, though in practice it is often replaced by oxcarbazepine. Although carbamazepine is structurally similar to the tricyclic antidepressant imipramine, it does not have antidepressant effects. It is used to treat focal and generalized tonic–clonic seizures, and in psychiatry, to treat mania (79). In recent years, it has been replaced by oxcarbazepine as a first choice for the treatment of focal seizures. Carbamazepine is converted to an active metabolite, carbamazepine epoxide, which also has some associated toxicity. Carbamazepine induces its own metabolism as well as that of several psychotropic agents. It can cause sedation, mild psychomotor slowing, and decreased attention and memory, even within the therapeutic range (80). Studies have demonstrated decreased performances on the continuous performance test (CPT) with carbamazepine exposure (61). However, other studies have found that this initial slowing improves after 1 month of treatment (81).

TABLE 7.2.4.7

COMMON ANTIEPILEPTIC DRUGS (AEDS) AND THEIR MECHANISMS OF ACTION

Drug	Major Mechanism of Action	Clearance	Indications
Carbamazepine	Blocks voltage-gated sodium channels	>95% hepatic	Partial seizures and GTC seizures
Clobazam	1,5 benzodiazepine; facilitates GABA-mediated inhibition	Extensively hepatic	Adjunctive for seizures associated with Lennox–Gastaut syndrome
Ethosuximide	Blocks Ca^{2+} channels	80% hepatic 20% renal	Childhood absence seizures
Ezogabine	Enhances transmembrane potassium current	Mostly hepatic 36% renal	Adjunctive, partial seizures
Felbamate	Unknown; blocks NMDA receptor	50% hepatic 50% renal	Adjunctive for seizures associated with Lennox–Gastaut syndrome

Gabapentin	Unknown; modulates Ca^{2+} channels	100% renal	Adjunctive for partial seizures
Lacosamide	Enhances slow inactivation of voltage-gated sodium channels	95% renal minimally hepatic	Adjunctive for partial seizures
Lamotrigine	Unknown; blocks voltage-gated sodium channels	85% hepatic	Partial seizures, GTC seizures, and seizures associated with Lennox–Gastaut syndrome
Levetiracetam	Unknown; modulates neurotransmitter release	Extensively renal	Adjunctive for partial seizures, GTC, myoclonic seizures (though often used as monotherapy)
Oxcarbazepine	Blocks voltage-gated sodium channels	45% renal 45% hepatic	Partial seizures
Perampanel	Blocks AMPA glutamate receptors	Extensively hepatic	Partial seizures and GTC seizures
Phenobarbital	Barbiturate; facilitates GABA-mediated inhibition	75% hepatic 25% renal	Partial seizures and generalized seizures
Phenytoin	Blocks voltage-gated sodium channels	>90% hepatic	Partial seizures and GTC seizures
Pregabalin	Unknown; modulates Ca^{2+} channel	Extensively renal	Adjunctive for partial seizures
Rufinamide	Unknown; promotes inactivated state of voltage-gated sodium channels	Extensively hepatic	Adjunctive for seizures associated with Lennox–Gastaut syndrome
Topiramate	Unknown; blocks voltage-gated sodium channels, modulates $GABA_A$, NMDA, and AMPA receptors; inhibits carbonic anhydrase	30–50% hepatic 50–70% renal	Partial-onset seizures and GTC seizures
Valproate	Unknown; may increase GABA concentrations; may block voltage-gated sodium channels	>95% hepatic	Partial seizures, GTC seizures, absence seizures, myoclonic seizures
Zonisamide	Unknown; blocks voltage-gated sodium channels	>90% hepatic	Adjunctive, partial seizures

Oxcarbazepine is structurally similar to carbamazepine and is used for many of the same seizure types. It is not, however, converted to the toxic, epoxide metabolite of carbamazepine and causes less induction of enzymes that metabolize other medications. There has been interest in its use for bipolar disorder but its efficacy, especially in pediatric bipolar disorder, has not been proven in clinical trials (82–85). It has been associated with only mild cognitive impairment.

Valproic acid (commonly administered as divalproex) is a potent broad-spectrum anticonvulsant effective in treatment of absence, generalized tonic–clonic, focal, and myoclonic seizures. Outside of the epilepsy field, it is also used in migraine prophylaxis, and for mood stabilization. It is highly protein bound and can displace other drugs that are protein bound, like phenytoin. It can inhibit the metabolism of

phenobarbital. These effects can lead to toxicity. It has a range of potential somatic AEs. Additionally, in therapeutic ranges it has been shown to cause impaired decision making and attention. In children, these effects can be more pronounced. Despite its efficacy in treatment of mania (86), it has also been known to cause aggression, irritability, and hyperactivity in some children in a dose-dependent fashion. In other children, however, it is quite effective in many epilepsy syndromes, and by monitoring AED levels, its side effects can be minimized.

Benzodiazepines, such as lorazepam, diazepam, clonazepam, and clobazam, are used to treat a range of seizures, and are administered as abortive agents to either abort prolonged seizures or to terminate seizure clusters. They can cause profound sedation and impairment. For example, clonazepam has been shown to cause decreased attention, irritability, hyperactivity, and disinhibition (87). Tolerance can develop after 1 to 6 months. These AEs are offset by the excellent efficacy of benzodiazepines in pediatric epilepsy syndromes.

Gabapentin is used for focal seizures, and has some efficacy against anxiety and chronic pain. It has essentially no drug–drug interactions (88). It is not useful for the treatment of mania. It can cause behavioral disinhibition, especially in children with pre-existing behavioral problems or intellectual disability.

Lamotrigine is a broad-spectrum anticonvulsant prescribed for the treatment of both focal and generalized seizures, and is used in bipolar disorder. Its clearance is inhibited by valproic acid and augmented by enzyme-inducing AEDs such as carbamazepine. Lamotrigine has been associated with a high risk of Stevens–Johnson syndrome, but the risk of this serious complication is decreased if lamotrigine is titrated upward slowly. If a rash occurs, the patient should be evaluated right away and serious consideration given to discontinuing the lamotrigine. Lamotrigine has some conflicting evidence linking Stevens–Johnson syndrome and toxic epidermal necrolysis to the HLA-B*15:02 allele (89–92), as do some other AEDs including oxcarbazepine (93). Sedation is not usually a problem with lamotrigine, even on initial titration. Lamotrigine causes little or no cognitive impairment, and as yet has no detectable effect on attention, psychomotor speed, or memory (80). In addition, some authors suggest it may even improve alertness (94). Lamotrigine has stimulant properties, and in a minority of patients, may cause tremulousness, irritability, aggressive behavior, and insomnia (78).

Levetiracetam is also a broad-spectrum anticonvulsant, and in many instances is the first-line treatment for new-onset epilepsy. Approximately 20% of children with epilepsy taking levetiracetam may have behavioral side effects such as irritability, anxiety, or depression. These symptoms are more likely in patients with developmental delay (95). On the other hand, in an open-label study in patients with autism, levetiracetam was found to have a favorable effect on attention, hyperactivity, and mood instability (65).

Topiramate is useful in the treatment of partial and generalized seizures. It is the

one newer AED for which there are significant concerns that it adversely affects cognition (96). Specifically, it has been found that it causes declines in word fluency and attention, and poorer attention after 1 month's treatment in young adults (97). Compared to pediatric clinical practice, higher doses and faster titration schedules are used in adult studies. Some suggest that the titration schedule may influence the degree of cognitive AEs. For example, in one such study patients were randomized to the addition of topiramate or valproic acid to already existing carbamazepine monotherapy (98). A slow titration schedule was used. Psychometric testing was done after 8 weeks. There was little difference in cognitive effects between the two drugs. Still, it is advisable to monitor an individual patient's response to topiramate and to monitor school performance. Psychiatric side effects such as depression, paranoia, and acute confusional psychosis have also been reported with topiramate. It can be associated with weight loss. An initial interest in the use of topiramate for bipolar disorder has not been substantiated in controlled trials.

Zonisamide is used to treat focal seizures. There is little sedation associated with this drug. Some patients lose weight because of decreased appetite. A study examining cognition in patients with refractory partial epilepsy before and during zonisamide treatment showed that high zonisamide plasma concentrations were linearly associated with deficits in verbal acquisition, but did not affect psychomotor abilities (99). Another study looked at patients on zonisamide or carbamazepine with phenytoin. There were lower verbal IQ and performance IQ scores in patients on zonisamide compared to carbamazepine (100). Here also, effect increased with dose.

PSYCHIATRIC DISORDERS IN CHILDREN WITH EPILEPSY

General Considerations

Children with epilepsy have high levels of psychiatric comorbidity. In a UK population-based study (101), 80% of children aged 5 to 15 years with active epilepsy were found to meet criteria for either cognitive impairment (IQ less than 85), or a DSM-IV-TR behavioral disorder, or both. In this study, the most prevalent neurobehavioral diagnoses were intellectual disability (40%), ADHD (33%), and autism spectrum disorder (21%).

The Isle of Wight study by Rutter et al. (102) found that children with idiopathic seizures showed a 29% rate of psychiatric disorders. In contrast, the rate for psychiatric disorders was 7% for children in the general population and 12% for those with other physical problems outside the CNS. In a population survey of more than 10,000 children aged 5 to 15 years in the United Kingdom, Davies et al. (103) found similar rates adjusting symptoms to DSM-IV. Psychiatric disorders were 37% in children with epilepsy, 9% in controls, and 11% in the chronic condition comparator, diabetes. More recently, Russ et al. (11) reported that children with

current epilepsy had statistically significantly higher incidence of depression (8% vs. 2% in children never diagnosed with epilepsy), anxiety (17% vs. 3%), ADHD (23% vs. 6%), conduct problems (16% vs. 3%), developmental delays (51% vs. 3%), autism spectrum disorder (16% vs. 1%), and headaches (14% vs. 5%). Children with epilepsy also had a higher risk of functional impairment, repeating a school grade, poorer social skills, higher parental aggravation, and frequently did not receive appropriate mental health treatment. Children with prior but not current seizures fared better, with intermediate risk.

Rodenburg et al. (104) conducted a series of meta-analyses, involving 46 studies and 2,434 subjects to examine the types and severity of psychopathology in children with epilepsy. They found a medium to large effect size of psychopathology for children with epilepsy compared to healthy controls. The researchers noted a smaller effect size for psychopathology when comparing children with epilepsy to those with chronic illnesses, leading them to conclude that some, but not all, of the psychopathology in epilepsy is attributable to a "generic feature" of chronic illness. Considering gender, some have found that chronically ill females tend to fare less well emotionally than chronically ill males, and have more suicidal thinking (105). As for treatment, it seems to be underutilized in this population (106). In order to improve recognition and treatment of psychiatric dysfunction in children with epilepsy, it is useful to consider the specific psychiatric disorders associated with epilepsy.

Autism and Epilepsy

The link between autism and epilepsy was first noted by Leo Kanner. The relationship between autism and epilepsy has been controversial. However, it is widely accepted now that there exist underlying brain conditions that predispose an individual to both conditions and frequent seizures can disrupt brain functioning and create autistic symptomatology (107). The incidence of epilepsy in autism has been estimated to range from 5% to over 30%, with a bimodal distribution in the age of onset. The first peak is before 5 years and the other after 10 years. There does not appear to be a gender difference (108). Any seizure type can be associated with autism.

The different subtypes of autism spectrum disorders have different rates of epilepsy. In classic autism, epilepsy has been found to develop in a third of children, with risk linked to intracranial pathology (108). The erstwhile diagnosis of childhood disintegrative disorder carried a risk of 70% for the development of epilepsy. In Rett syndrome, over 90% of patients have epilepsy (109).

A specific EEG pattern that correlates with autism has not been found. About 10% of children with autism have a paroxysmal EEG pattern, such as that found in LKS or with electrical status epilepticus in sleep. EEGs are not routinely requested for

patients with autism. A retrospective study by Gabis et al. (110) examined the EEG findings in 56 children with pervasive developmental disorders to examine the value of obtaining an EEG in this patient population. They found that only two children without clinical seizures, or a history of language regression, as in LKS, had an epileptiform EEG. In general, a patient who has autism and displays paroxysmal stereotyped behaviors raises the suspicion of epilepsy. In addition to EEG, home or school videos are helpful to clarify the event. If regression is present, then an EEG should be obtained. A higher index of suspicion is warranted in those patients with autism who are lower functioning or severely impaired, as seizure disorders are more common and more treatment resistant in those with greater intellectual impairment (107,111).

Depression and Anxiety

As in adults, depression and anxiety are commonly found in children with epilepsy. In a study by Vega et al. (112), as compared to healthy matched controls, children aged 6 to 16 years with childhood absence epilepsy (CAE) had higher rates of depression and anxiety symptoms and more general psychosocial difficulties like isolation and low self-esteem. Caplan et al. (113) interviewed 100 children with epilepsy and found that 33% had a depressive or anxiety disorder. Those with mood and anxiety disorders had lower IQ scores. Only 33% of those with identified disorders had received prior mental health treatment, which is surprising given their involvement in the health care system as a result of their epilepsy. Other studies have found depressive symptoms to be the most common psychiatric symptom in children with epilepsy (114).

A variety of factors have been proposed and studied to explain depression in epilepsy, yielding contradictory results. The epilepsy factors include age of onset, duration of epilepsy, seizure type, and seizure severity. Iatrogenic factors include treatment with AEDs and surgery. Psychosocial factors include stigma, discrimination, sense of control, attributional style, and social supports. Ultimately, the likely explanation is multifactorial (115). The etiology of anxiety is less well explored. Some have considered the role of limbic structures, which include the amygdala and hippocampus, as an area of pathogenesis for anxiety (116).

Suicide

In adults, rates of suicide or self-harm in those with epilepsy are thought to be five times that of the general population, with the highest risk for those with temporal lobe epilepsy (117). Lambert and Robertson (115) reviewed studies that examined causes of death in epilepsy and found that the rate of death by suicide was 10 times that of the general population. The data in children also suggest high rates of suicidal

thinking or behavior. A chart review of pediatric suicide attempters with epilepsy found a rate 15 times that of the general population (118). In the Caplan study cited above, 20% of the subjects reported suicidal thinking, compared to 9% of controls. Of those with suicidal thinking, 37% had plans. Those with disruptive behaviors, comorbid with depression and anxiety, were 12 times more likely to have suicidal thinking. Duration of illness also corresponded to suicidal thinking.

In a British population-based retrospective cohort study that attempted to estimate the magnitude of the association between suicide and epilepsy, the researchers found that the association exists even before epilepsy manifests, suggesting a common underlying biology rather than the effects of the seizures or AEDs (71).

Psychosis

Psychosis and its relationship to epilepsy have generated a robust literature. Since the mid-19th century, there have been generally two lines of thinking regarding psychosis. In one, epilepsy and active psychosis are thought to be incompatible. ECT for the treatment of psychosis emerged in part from this perspective. The other line of thought views epilepsy as coexisting with or facilitating psychoses (116). The concept of forced normalization and alternative psychoses introduced by Landolt illustrates a reciprocal coexistence (119); patients whose EEGs were abnormal but which normalized with treatment were observed to develop psychopathology. Slater et al. (120) described schizophrenia-like psychoses related to duration of epilepsy and amount of brain damage; this association was especially strong in temporal lobe epilepsy. Support for the relationship of epilepsy and psychosis is found in genes that overlap both conditions (5–7). The concept of kindling as an etiologic theory for epilepsy may also help explain the emergence of psychotic phenomena (121).

Psychotic symptoms have been considered according to their temporal relationship with seizure activity; that is, whether they are preictal, ictal, postictal, or interictal. The psychiatrist is most likely to be concerned with interictal presentations of psychosis, although the hospital-based consultant may be called in during any of the other states. Occasionally, the hospital-based psychiatric consultant may be the first to evaluate a psychotic presentation, before the epilepsy history is revealed through chart records, by a late-arriving family member, or by the patient himself after he recuperates.

There are no epidemiologic studies examining the comorbidity of psychosis and epilepsy in children. Adult studies have methodologic limitations but provide some information. A recent systematic review and meta-analysis by Clancy et al. (122) pertaining to prevalence rates of psychosis in epilepsy concluded that up to 6% of individuals with epilepsy have a comorbid psychotic illness and that such individual with epilepsy have an eightfold increased risk of psychosis. Mendez et al. (123) retrospectively compared outpatients in a neurology clinic with epilepsy or migraine

headaches. They found that 9% of the patients with epilepsy had interictal schizophrenia symptoms, versus 1% of the patients with migraine. Shaw et al. (124) found that 3% of patients with temporal lobectomy for intractable seizures developed schizophrenia-like psychoses.

In addition to methodologic issues, studies and descriptions of psychotic states in epilepsy patients have been plagued by matters of semantics in describing both psychotic symptoms and epilepsy. Parnas and Korsgaard (125) observed in 1982 that the descriptions of psychosis seldom fit the bleulerian definition of schizophrenia and advised against the use of the term schizophrenia-like to describe psychoses in epilepsy. With this concern in mind, Kanemoto et al. (126) set out to reexamine the matter of interictal psychoses using DSM-IV criteria definitions of psychotic disorders in conjunction with the ILAE classification criteria. In a retrospective review of all outpatient records from 1984 to 1999 at their regional epilepsy center, they found 132 patients to have interictal psychoses, or 4.5% of all patients. The researches excluded ictal or postictal psychotic phenomenon. Schizophrenia was found in 1.9% of the total sample. Temporal lobe epilepsy made up the vast majority of seizure types with psychosis, accounting for 56% of cases. The patients with schizophrenia were more likely to have had early-onset psychosis (<20 years old) and to have lower IQ. One significant limitation of the study is its retrospective design.

An epidemiologic question mark remains for both adults and children regarding epilepsy and psychosis. The sum of the data suggests that perhaps interictal psychotic states are more commonly seen than would be expected in the general population and that temporal lobe epilepsy seems to be the predominant type accountable for this.

ADHD and Disruptive Behavior Disorders

Symptoms of ADHD in epilepsy syndromes tend to be ones of inattention rather than hyperactivity–impulsivity. Some suggest that ADHD and epilepsy share common risk factors and that both may share common neuropsychological impairments, especially the inattentive type (127). Others have also observed that a number of children with uncomplicated ADHD and without epilepsy have epileptiform discharges (128). In a study on psychiatric disorders and behavioral characteristics of pediatric patients with epilepsy and ADHD, the comorbidity (including anxiety disorders and oppositional defiant disorders) in those patients was similar to that of ADHD without epilepsy (129).

Several studies have examined the prevalence of ADHD in epilepsy populations. In one, a history of ADHD was 2.5 times more common in children newly diagnosed with epilepsy compared to controls (3). In another, Dunn et al. (130) found that 25% to 37% of children and adolescents scored in the clinical range on the attention scale of the Child Behavior Checklist (CBCL); using a symptom inventory which gives

symptom profiles according to DSM-IV, they found 24% of children had symptoms consistent with ADHD, predominantly inattentive type, and 11.4% with ADHD, combined type. In the UK population study by Davies et al. (103), the rate of DSM-IV ADHD in complicated epilepsy was 12% and in uncomplicated epilepsy, 0%, suggesting degree of illness may account for ADHD symptoms. As with ADHD symptoms in the general population, these symptoms lessen with age also for patients with idiopathic epilepsy and ADHD, probably because development and brain maturation have a similar positive effect on attentional issues in children with epilepsy (131).

The data for other disruptive disorders are generally embedded in data on ADHD. Caplan et al. (132) found ADHD, oppositional defiant disorder, or conduct disorder in 25% of patients with complex partial epilepsy or generalized primary seizures. Ott et al. (1) found disruptive behavior disorders in up to 23% of those with complex partial epilepsy or primary generalized seizures.

Neuropsychological Functioning and Education

The literature generally suggests that epilepsy negatively impacts cognitive functioning. Although findings are variable, this is related to specific epilepsy syndromes, age of onset, duration, seizure frequency, and number of AEDs.

Williams et al. (133) found that children with epilepsy had a full-scale IQ in the low average to average range. O'Leary et al. (134) also found that children with epilepsy had lower IQs. They administered the WISC-III to 32 child patients with epilepsy, without comorbid conditions and IQ greater than 70, and to matched controls and found a mean difference of one standard deviation on the full-scale IQ, 107 versus 92. Høie et al. (135) studied nonverbal intelligence in 198 children with epilepsy using Raven matrices. Severe nonverbal performance problems were found in 43% of children with epilepsy, compared to 3% of controls. These studies reflect group trends and do not reflect how an individual child will perform; for example, Smith et al. (136) also found IQs in the low to average range, but individual scores ranged from the <1% to >99%.

Regarding IQ stability, Bourgeois et al. (137) prospectively followed children yearly over 4 years, administering their first psychological evaluation within 2 weeks of initial diagnosis. They found that overall IQ did not decrease, but that in a subset of subjects, IQ scores persistently showed a decrease of 10 points or more. This was related to a higher incidence of drug levels in the toxic range, difficulty controlling seizure activity, and an earlier age of seizure onset. Rodin et al. (138) readministered the WISC to children with epilepsy 5 years after initial testing and found that WISC IQ estimates decreased slightly over time; they suggested that decreased mental growth rather than loss of function was responsible.

Regarding education and achievement, Farwell et al. (139) studied 118 children

with epilepsy and found they had repeated a grade or been placed in special education at twice the normal rate. In this study, years of seizure activity correlated with lower intelligence. Aldenkamp et al. (140) examined several factors related to achievement and concluded that epilepsy type is the main factor underlying educational achievement. They speculated that since epilepsy type is correlated with intelligence, this may be the primary cognitive factor underlying educational underachievement. Regarding achievement, it seems that only those children with high severity epilepsy have lower school–administered achievement scores compared to national norms, but not those children with inactive or low-severity epilepsy (141). Whether epilepsy (or more generally, the presence of a chronic condition) itself affects achievement has also been studied; those with epilepsy generally do less well (142).

Learning Disorders

Difficulties in reading, writing, and mathematics may be found in one-third of children with epilepsy (143). One study examining children with epilepsy found that academic problems were highest in math, followed by spelling, reading, and comprehension. Children also did less well than expected for age and IQ level (144). Seizure onset in the language-dominant hemisphere is thought to affect reading comprehension, written language, and calculation abilities, more so than seizure onset in the nondominant hemisphere (145).

Family

Rodenburg et al. (146) in a literature review found that compared to control children, families with a child with epilepsy had a lower quality of parent–child relationship, more depression in mothers, and had problems with family functioning. Family factors seem to be stronger predictors of psychopathology than epilepsy-related factors (147).

Quality of Life

Adolescents' perceptions of epilepsy can be highly negative. Cheung and Wirrell (148) interviewed healthy controls and children with chronic conditions. When asked about the physical and social impact of eight chronic diseases (epilepsy, leukemia, HIV infection, Down syndrome, migraine, asthma, diabetes, and arthritis), epilepsy was viewed as having a worse physical impact than all illnesses except Down syndrome. The perceptions included the view that epilepsy commonly causes mental handicap and commonly leads to self-injury and death or injury in others. In addition, healthy controls viewed individuals with epilepsy as less honest, popular, fun, and

less adept at sports than healthy teens.

Children with epilepsy often have a poorer self-concept than do those with other chronic conditions (149–151). Older adolescents perceive a greater negative impact on life and general health and have more negative attitudes about epilepsy. Those with severe seizures and female patients seem to have the greatest difficulty (152). Each AED also has its own side-effect profile which may impact self-esteem, such as weight gain. Mitchell (153) argued, however, that family, socioeconomic, and cultural factors are the primary determinants of social, academic, and other problems in epilepsy and that medications, seizures, or cognition play a minor role.

TABLE 7.2.4.8

RECOMMENDATIONS FOR COMMONLY USED PSYCHOTROPICS IN THE CHILD WITH A SEIZURE DISORDER

Medication or Class	Recommendations (Low Seizure Risk ≠ Absent Risk)	Key Drug–Drug Interactions with AEDs
First-generation antipsychotics	Use not advised for chlorpromazine and loxapine Use others judiciously Haloperidol has lowest risk	Carbamazepine, phenobarbital, phenytoin, and perhaps oxcarbazepine may reduce levels through cytochrome P450 3A4 induction
Second-generation antipsychotics	Use not advised for clozapine Seizure risk low for others	Risperidone, quetiapine, aripiprazole, and ziprasidone may be reduced by above AEDs through 3A4
SSRIs/SNRIs	Seizure risk low Venlafaxine may have increased risk over others	Fluoxetine and fluvoxamine may increase carbamazepine levels through 3A4 inhibition
Trazodone	Seizure risk low	Substrate of 3A4; above AEDs may reduce
Alpha agonists	Seizure risk low	No known drug interactions with AEDs
Bupropion	Use not advised	Phenytoin and phenobarbital may reduce levels through 2B6 induction
Atomoxetine	Seizure risk unclear. Use judiciously	No known drug interactions with AEDs
Lithium	Use judiciously. Considered proconvulsant	Neurotoxicity with carbamazepine and phenytoin
Stimulants	FDA contraindicates when comorbid seizures are present, but data suggest they can be used judiciously	No known drug interactions with AEDs
TCAs/tetracyclic antidepressants	Use not advised for clomipramine, amoxapine, and loxapine Use others judiciously	Valproate may increase and carbamazepine may decrease TCA levels
Benzodiazepines	Anticonvulsant, but proconvulsant if suddenly discontinued	Alprazolam, diazepam, midazolam, and triazolam are substrates of 3A4

Driving restrictions may impact adolescents with epilepsy. Restrictions on driving after a seizure are mandated by law and vary from state to state, usually lasting 3 to 12 months after an index seizure. If no new seizures occur during the restricted time, driving privileges are reinstituted (154).

Examining outcome, Jalava et al. (155) followed a cohort of childhood-onset epilepsy into adulthood with a mean follow-up of 35 years. They found that those with epilepsy and no other neurologic problems did less well than controls in education, employability, marriage rate, and—depending on seizure activity and polypharmacy—satisfaction with present life.

PSYCHOPHARMACOLOGICAL TREATMENT OF CHILDREN WITH EPILEPSY AND COMORBID PSYCHIATRIC DISORDERS

Psychopharmacologic treatment in children with epilepsy should always be embedded in a full biopsychosocial approach to the child's problems. Different domains of dysfunction should be conceptualized and each given treatments specific to that domain. Thus, academic and social skills deficits may require remediation. School failure may require modification of the educational plan. Relationship problems benefit from psychotherapy, as will low self-esteem and coping difficulties. Family and individual misconceptions should be countered with psychoeducation. The primary symptoms of the patient's DSM-5 disorder may, depending on the disorder, benefit from psychotherapy or psychopharmacology, or both.

When the time comes to choose a psychopharmacological agent, four considerations should be borne in mind: efficacy, seizure threshold, interactions, and AEs. Considering efficacy first, for nearly all the psychiatric disorders comorbid with epilepsy, specific randomized controlled trials in children with epilepsy plus that disorder have not been done. Thus clinicians will need to use, as a guide, the efficacy data from children without seizures, but more circumspectly. Similarly, while many psychotropics have been assumed to lower the threshold for having a seizure, randomized controlled data, with the exception of methylphenidate, does not exist for the risk of exacerbating seizures. For most psychotropics, practitioners must rely on the FDA trial data for that agent, by comparing the rate of new-onset seizures in patients receiving active medication to the rate in those receiving placebo (even though patients with epilepsy are excluded from almost all these trials). Other ways to estimate the risk include considering the rate of seizures when the psychotropic has been taken in an overdose and examining the literature for uncontrolled case reports and case series.

Drug–drug interactions between psychotropics and AEDs can be pharmacodynamic (e.g., additive sedation) or pharmacokinetic (e.g., decreased antipsychotic plasma level when the patient is taking carbamazepine). These interactions must be considered when adding or removing an AED or a psychotropic. It is useful to anticipate that the rate of AEs from a psychotropic might be higher in

patients with epilepsy than in patients without it. This will result in a frank discussion of risks with the family and "starting low and going slow" with the psychotropic. Table 7.2.4.8 summarizes recommendations for the more commonly prescribed psychotropics when epilepsy is comorbid.

Just as we would not have a patient's seizures go untreated, we and our colleagues in neurology should not overlook the psychiatric and psychological comorbidities commonly present in children with epilepsy, and ensure that these do not go undiagnosed and untreated.

CHAPTER 7.2.5 ■ LIFE-THREATENING ILLNESS, PALLIATIVE CARE, AND BEREAVEMENT

JOHN P. GLAZER, MARYLAND PAO, AND DAVID J. SCHONFELD

INTRODUCTION

"Although the world is full of suffering, it is also full of the overcoming of it."

—Helen Keller

While 42,000 infants, children and adolescents died in 2013 (1), an estimated 500,000 children are currently living with life-threatening conditions (2). This reflects evolving medical and technologic advances resulting "in children living longer, often with significant dependence on new and complex technologies (3)." The modern hospice movement began in the 20th century with Dame Cicely Saunders' groundbreaking work at St. Christopher's Hospice, London, on behalf of adults dying of cancer, came to the United States in the 1970s, proliferated rapidly, and more recently was extended to children (2,4).

Over the past two decades pediatric hospice care has broadened so that now the World Health Organization (WHO) (5) defines pediatric palliative care (PPC) as "… the active total care of the child's body, mind and spirit, and also involves giving support to the family. Optimally, the care begins when a life-threatening illness is diagnosed, and continues regardless of whether or not a child receives treatment directed at the underlying illness." This definition differs fundamentally from that traditionally, and currently, applied to adults by the Center for Medicare and Medicaid Services (CMS), which authorizes reimbursement for palliative care services only when a patient's life expectancy is less than 6 months (6). But estimating prognosis for children with life-threatening illness is notoriously unreliable. Increasing recognition of this medical reality, and mounting evidence that children and families are far better served when palliative care services are introduced at the time of diagnosis regardless of predicted outcome, led to the seminal conceptual and clinical advance of section 2302 of the Patient Protection and Affordable Care Act of 2010 (ACA) (7). Under ACA, families and providers of children with life-threatening conditions no longer have to forego curative treatments to qualify for palliative care services under Medicaid.

This chapter addresses the principles and practice of pediatric palliative medicine, bereavement, whether or not in the setting of life-threatening illness, and illustrates the role of the child and adolescent psychiatrist in the context of increasing recognition of the central importance of these issues in clinical practice. Regarding palliative care, the understanding that "palliative care is not all about death" (8) is

supported by a growing body of evidence demonstrating the efficacy of PPC as well as by recent policy positions of leading professional organizations speaking on behalf of children and families, including the American Academy of Pediatrics (AAP) Policy Statement: Pediatric Palliative Care and Hospice Care Commitments, Guidelines, and Recommendations (4), WHO: *Guidelines on the Pharmacological Treatment of Persisting Pain in Children with Medical Illnesses* (9), and the National Hospice and Palliative Care Organization (NHPCO) on Pediatric Palliative Care (10). In addition, "Pediatric Psychosocial Standards of Care for Children with Cancer and their families" was released in December 2015 and includes an evidence-based palliative care standard for children (11). These policy advances recognize both the unpredictability of medical prognosis in children with life-threatening illness, and the role of hope, "the weight of a feather on the side of optimism" as Solnit put it more than 30 years ago (12), noting the denial of hope differs crucially from a realistic appraisal and acceptance of life threat.

Himelstein et al. (2) have proposed the following "essentials" of PPC (Figure 7.2.5.1): (1) physical concerns such as pain assessment and management; (2) psychosocial concerns, including child and family fears, communication and coping styles; (3) spiritual concerns; (4) advanced care planning, including identification of decision-makers, illness trajectory, care goals, and end-of-life care; (5) practical concerns regarding location of care and familiarity with the child and family's community and school environment; and finally, (6) bereavement care for families if the child dies. Communication with and among the ill child and his or her family members and providers, and complex relationships between pain and psychiatric symptom expression, are central to the focus and expertise of the child psychiatrist in a medical setting, as is the grounding of care longitudinally. As such, child and adolescent psychiatry and pediatric palliative medicine are natural partners in the management of children with life-threatening illness.

SCOPE

This chapter addresses psychiatric aspects of pediatric life-threatening illness through review of cognitive-developmental acquisition of concepts of death, pain, and symptom management in the life-limited child, the needs of the parents, siblings and providers of these children, assessment, and management of comorbid psychiatric symptoms and disorders, bereavement, parental loss, and approaches to systems of care. Equally vital is the creation of curricula in medical schools and residency programs to ensure graduates' literacy in this critical dimension of medical practice. "Palliative care" and "bereavement" are meant as inclusive terms: As children with life-limiting illness live longer, with advances in chemotherapy, transplant technology, radiation oncology and other modalities, old distinctions blur. To palliate is to "relieve pain and distress" without cure (13); as already noted, this

definition is expanded to include children with life-limiting illness who survive and those who do not. Similarly, bereavement is “a deprivation causing grief and desolation, especially the death or loss of a loved one” (13). In addition to the 40 to 50,000 children and adolescents who will face their own deaths each year in the United States, another 4% of children will lose a parent before age 15 years (14). Professionals responsible for the care of children must address the psychosocial needs of children and families in all of these settings. Speaking to the experience of children and families with life-limiting illness more than 30 years ago, Solnit wrote “the adults and the children don’t know whether to prepare for life or for death” (12). The principles discussed here address the universal experience of separation and loss by children, whether they, their parents, or their siblings have a life-limiting illness from which they may recover or die. One other semantic distinction should be mentioned, that of “life-threatening” and “life-limiting”; these have been defined as conditions that potentially threaten life, and those that definitely do. The authors will exclusively use the term life-threatening in the text following to broadly denote both.

CHILDREN’S CONCEPTS OF DEATH

Children experience life-threatening illness in themselves or others through the prism of psychological, physical, and social development. Health professionals must therefore approach such children and their families with expertise in child and adolescent development and family systems (2). Central to this approach is an appreciation of the developmental acquisition of the concepts of death (15,16). The stages in children’s understanding of the concepts of death have been well studied (17–21). Four major concepts related to death have been noted consistently: irreversibility, finality (also termed nonfunctionality), causality, and inevitability (also termed universality). Acquisition over time of a mature understanding of each of these concepts inevitably shapes a child’s response to life-threatening illness in the child or loved ones. Speece and Brent (20) concluded that most studies found the age of acquisition of the three concepts they reviewed (irreversibility, nonfunctionality, and universality) to occur between 5 and 7 years; earlier studies citing an older age of acquisition were noted to have significant methodologic flaws.

Since infants have been shown to respond to maternal depression with altered feeding patterns and failure to thrive, it is not surprising that they can similarly respond to the affective tone within the household after the serious illness or death of a family member (22). In this way, infants and toddlers are capable of reacting to someone else’s death, even if they “understand” little of what has occurred. But once infants have developed object permanence, they are capable of appreciating the permanence of loss. It is therefore probably no coincidence that infants and toddlers engage universally in the game of peek-a-boo (or hide and seek) which has been suggested may be an attempt for children to understand and cope with separation and

loss. Indeed, the translation for “peek-a-boo” from Old English is literally “alive-or-dead” (23,24).

Infants, toddlers, and young children generally equate death with disappearance or separation. However, when faced with traumatic events, such as the death of a parent or other family member, some children 2 to 3 years of age or even younger have been able to demonstrate a beginning understanding of some of the concepts of death. In general, the role of personal exposure to the death of others has been controversial; although several studies have shown that such personal experience may promote the acquisition of the concepts of death (25,26), other studies have failed to support this conclusion (27,28). Cross-cultural comparisons (29–31) have illustrated both cultural variations and important cross-cultural consistencies, suggesting that although the underlying developmental framework is likely to be robust across cultures, sociocultural variables may have a significant impact on the rate of acquisition of individual concepts. In addition, developmentally based and conceptually focused education has been demonstrated to have a positive impact on children’s rate of acquisition of these concepts (32).

From preschool age to early childhood, children continue to clarify their concepts of death but are still confused at times, remaining prone to misconceptions and literal misinterpretations. Children in this age group with a life-threatening illness have been shown to have a marked awareness of the seriousness of their illness, even if never told that their illness is fatal, and often develop a conceptual understanding of death more typical of an older child (33,34).

During adolescence, reactions to life-threatening illness are influenced both by emerging formal operational cognitive capacities for abstract thought and by intense developmental striving for physical, sexual, social, psychological, and intellectual independence and mastery. Life-threatening illness turns this developmental process on its head, bringing physical immobility and dependence rather than independence, isolation from peers rather than the forging of new relationships, and may stop educational progress in its tracks.

Practice sphere	Area of Assessment	Plan
Physical Concerns	Identify pain or other symptoms	Create and disseminate pharmacologic and nonpharmacologic treatment plan Place emergency medications in the home Refer child to pain and palliative care specialists as needed
Psychosocial Concerns	Identify child and family's fears and concerns	Address child and family's fears and concerns honestly Assure child and family they will not be abandoned Address concerns of child's siblings and extended family
	Identify child's coping and communication styles	Adjust care plan to meld with child and family's coping and communication styles Communicate with child in a developmentally appropriate fashion Explain death concepts and developmental stages of death understanding
	Discuss previous experiences with death, dying, other traumatic life events, special issues such as substance abuse or suicidality	Modify care plan and choices on the basis of child's previous experiences Consider referring child and family to mental health professionals as needed
	Assess resources for bereavement support	Make plan for follow-up of family after child's death Assure family members they will not be abandoned
Spiritual Concerns	Perform a spiritual assessment (review child's hopes, dreams, values, life meaning, view of role of prayer and ritual, beliefs regarding death)	Consider referring child to culturally appropriate spiritual care provider Offer to help explain child's illness to spiritual provider; with family's permission Allow time for child and family to reflect on life's meaning and purpose
Advance Care Planning	Identify decision makers	Include key decision makers Communicate decision-making information to entire team
	Discuss illness trajectory	Provide information as necessary to make the subject understandable Establish consensus regarding illness trajectory Identify effect of illness on child's functional capacity and quality of life Identify probable time until death
	Identify goals of care	Establish whether goals are curative, uncertain, or primarily comfort Communicate goals to health care team
	Think about issues regarding care or concerns near end of life	Create or disseminate medical plan (including do-not-resuscitate orders as necessary), reflecting choices for specific interventions related to change in health status Provide anticipatory guidance regarding physical changes at time of or near death, whom to call, who will manage child's symptoms
Practical Concerns	Establish means of communication and coordination with health care team	Identify care coordinator and route of contact that is always available Recruit new personnel as needed to achieve goals (such as hospice or palliative care specialists) Make plan-of-care information available to team
	Establish child and family's preferences for location of care	Assure child or family that stated goals of care can be achieved in preferred environment Create and disseminate plan for location of death, contacts at time of death, and pronouncement of death
	Become familiar with child's home or school environment	Create and disseminate care plan for all relevant environments Try to visit care sites such as school to provide education and support, if possible in partnership with community
	Address child's current and future functional status	Order medical equipment such as wheelchair, suction, commode, or hospital bed for anticipated needs
	Inquire about the financial burden child's illness places on family	Offer assistance from social services, financial counselors, or other supports as available in the community

FIGURE 7.2.5.1. Essential elements in the approach to pediatric palliative care. (From Himelstein BP, Hilden JM, Boldt AM, Weissman D: Pediatric palliative care. *N Engl J Med* 350:1752–1762, 2004. With permission.)

Cassel's compelling conceptualization of suffering is that of a state of distress specifically and individually linked to a sense that a person's intactness or integrity is threatened or disrupted, that lasts until the threat is gone or intactness restored (35). Fundamental to child and adolescent psychiatry is the notion that when a child's "intactness or integrity" is threatened or disrupted, so is that of the family. Suffering is an apt organizing principle around which pain and symptom assessment and management in children and youth at or near the end of life can be organized diagnostically and therapeutically.

In a cohort of 103 parents of children who died of cancer interviewed a mean of 3.1 years after the child's death, 89% of the children were judged to have suffered "a lot" or "a great deal" from pain, fatigue, or dyspnea while only 27% of parents reported treatment to have been successful (36). Pain may be considered the symptom most often attended to by patients, families, and providers in the palliative care setting. The assessment and treatment of pain in pediatrics and PPC has been extensively investigated, and foundational principles in assessment and treatment have emerged, with a great deal more evidence to guide clinical practice than in the previous edition of this text.

The International Association for the Study of Pain defines pain as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage" (37). Crucially, this definition recognizes that emotional factors are inherent in children's experience and expression of pain, and that its perceived magnitude varies according to factors not limited to the extent of measurable tissue damage.

The historic underrecognition and undertreatment of pain in children and its adverse medical and emotional consequences are well documented (38). Eland's pioneering work in the 1970s (39) found in a chart review of 25 children undergoing major surgery (traumatic amputation, nephrectomy, cleft palate repair) at a major children's hospital, 13 of them received no postoperative analgesia at any point in their hospital stay. Among the 12 children who did receive analgesic drugs, only 24 total doses were given, compared to 372 opioid and 299 nonopioid analgesic doses given to a comparison series of 18 adult postoperative patients. Reflecting prevailing attitudes toward the experience and management of pediatric pain as late as the 1960s, Swafford and Allan reported that just 26 of 180 children (14%) admitted to a pediatric intensive care unit over a 4-month period "required" opioid analgesia, stating "pediatric patients seldom need medication for the relief of pain. They tolerate discomfort well. The child will say he does not feel well or that he is uncomfortable, that he wants his parents but often he will not relate the unhappiness to pain" (40).

Pediatric pain assessment and management have improved dramatically over time, particularly after Anand et al.'s pioneering studies in the 1980s showed that preterm infants undergoing surgery with minimal anesthesia exhibited marked physiologic

stress responses, with adverse effects on morbidity and mortality (41). Pain management in children with life-threatening illness continues to be challenging, as reported by Wolfe et al. in the study cited earlier of a cohort of parents whose children had died a mean of 3.1 years prior (36). The authors concluded that while by 2000, PPC had become the standard of care, it was still unclear whether the care of children with cancer met that standard, concluding that treatment (of pain and other end-of-life symptoms) was "seldom successful, even in the case of symptoms that are typically considered to be amenable to treatment." Reflective of advances made since that study was published, a follow-up study by the same authors using a similar design, published 7 years later, after establishment of a formal PPC service at Boston Children's Hospital-Dana Farber Cancer Institute in 1997, found significant improvement in parent beliefs about the efficacy of pain control in their children in the later cohort (42). Since inadequately treated pain is well known to mimic psychiatric symptoms such as anxiety and depressed mood, the role of the child and adolescent psychiatrist is central to assessing the subtle interplay between pain and psychiatric symptomatology to ensure that the appropriate treatment intervention or interventions are employed, whether for psychiatric disorder, pain, or both (43).

Pain Assessment

Pain is common in children in palliative care settings, at a prevalence of 75% in a retrospective chart review study of symptoms in children dying with cancer in Japan (44), comparable to rates found in other studies in the United States (36,45).

Pain assessment in children with life-limiting illness has recently been reviewed (46,47). As noted by Schechter (48), while developmentally appropriate assessment is the "cornerstone" of pediatric pain management, the advent of developmentally sensitive instruments is recent and challenges remain, including the limited capacity of younger children to report pain directly. McCulloch and Collins (46) include the following major factors in clinical pediatric pain assessment: (1) developmental stage, (2) intelligence, (3) personality, (4) temperament, (5) previous pain experience, (6) expectation and acceptance of pain, (7) child and parent coping strategies, anxieties, and cultural background, and (8) prognosis. Clinical studies suggest that most children can identify presence and location of pain by age 2, and pain intensity by age 4 (46,49–51), can participate in formal pain ratings by age 5, and are able to describe the quality of the pain experience by age 8 (46,52–54).

In clinical settings, children age 5 or older are typically able to utilize either a 10-point visual analog scale (VAS) or face-based severity scale (47,55). In Piagetian terms, 8 year and older preadolescent children at a concrete operational level of cognitive development would be expected to have a simple, internalized symbolic capacity to rate pain severity, thus the utility of numeric visual measures (46), and as noted, even younger children appear to be equally capable, perhaps due to cognitive

advancement related to being seriously ill itself. Several well-validated measures appropriate for preoperational 3- to 8-year-old children have been developed (55–57). Fortunately, measures specifically applicable to children with cancer as young as age 2 are now available (58,59).

TREATMENT

Pharmacologic

A cornerstone in addressing the pharmacotherapy of pain is the analgesic ladder of the WHO (60) which is applicable to children (60,61). Consistent with the central principles of best practices and evidence-based medicine, the classic "three-step" model has recently been reformulated by the WHO Guideline Review Committee as a two-step model, chiefly due to the "step 2" "weak" opioids codeine and tramadol failing to meet Committee standards. There are no data to support the safe use of codeine in children, and rates of conversion from the prodrug to its active metabolite morphine vary by ethnicity and across individuals depending on "slow," "intermediate," or "rapid" metabolism. Recent concerns about potentially lethal complications of codeine in children led the FDA to issue a warning about its use in children undergoing tonsillectomy (62). There are no robust safety or efficacy data on the use of tramadol in pediatric patients in PPC settings either (63). The change from a "three-step" to a "two-step" model are set down in the *WHO Guidelines on Pharmacological Treatment of Persisting Pain in Children with Medical Illnesses* (9). The WHO analgesic ladder grades pain severity and matches an analgesic category to each level: acetaminophen or NSAIDs, with or without an adjuvant, for mild pain, and potent opioids, morphine being the paradigm, with or without an adjuvant, for severe pain. "Adjuvants" include a broad range of drugs whose primary indication is not pain management but may be efficacious in selected pain syndromes, and may include anticonvulsants, antidepressants, corticosteroids, psychostimulants, and neuroleptics, among others (47).

The WHO guidelines set forth the following principles of analgesic pharmacotherapy (63):

- By the *ladder*, using the new two-step approach
- By the *clock*, using regular dosage intervals and refraining from "PRN" orders
- By the *appropriate route*, preferably oral or other noninvasive routes
- By the *child*, taking the individual child into account

Pain management must also take into account whether the focus of treatment is *somatic or nociceptive* (acute and visceral), where the nervous system is intact, or *neuropathic* pain, when it is not, as different classes of analgesics may be indicated in each. Children in palliative care settings typically exhibit both subtypes, with more

robust data available for somatic/nociceptive than for neuropathic pain.

Major strides in empirically supported pediatric pain management principles in the past 5 to 10 years provide new opportunities including the use of different drugs, and novel methods of opioid delivery, including subcutaneous, sublingual, buccal, and intranasal routes (64). New drug classes include the NMDA-receptor antagonist ketamine which may have potential in the treatment of pediatric neuropathic pain (65) and alpha-2-agonists such as clonidine and dexmedetomidine (66–68). The unique selective serotonin/norepinephrine reuptake inhibitors duloxetine and venlafaxine show promise in managing pain in adults, with minimal evidence for pediatric patients.

Challenges in pediatric pain management include limitations of the new WHO guidelines, in the evidence base, and in drug availability worldwide. For example, the WHO guidelines focus on morphine as the opioid of choice, yet it is not available in many parts of the world, whereas Tramadol is widely available and has potential advantages in its oral bioavailability, serotonergic properties, and possibly safety advantages over morphine (63). Despite potential advantages in newer treatments for neuropathic pain, the evidence base remains sparse, even for the popular gabapentinoids gabapentin and pregabalin. Interest in a potential role for psychostimulants such as methylphenidate in improving fatigue in terminally ill patients has been tempered by a recent Australian *N*-of-1 trial in 43 adults failing to demonstrate statistically significant efficacy, though 8 subjects reported "important" improvement (69). Finally, a cautionary note about opioids: with the dramatic rise in opioid-induced deaths in recent years, constituting a public health emergency, and lack of evidence for opioid safety or efficacy in treating chronic, rather than acute, pain, it is critical for physicians caring for children both to be assertive in prescribing opioids for severe, acute pain, and cautious in minimizing risk of overdose and nonefficacy for chronic pain (70).

Psychological and Behavioral

"Health professionals cannot choose to avoid using psychology to treat pain." McGrath and coworkers' formulation (71) provides a useful working model of the role of an array of psychological interventions for managing pediatric pain. The evidence base is limited but growing, and as McGrath (71) notes, "informal psychological interventions accompany every medical intervention … our choice is whether to use psychology in a conscious, constructive fashion or to leave the psychological aspect of our interventions to chance." The task of pain management for seriously ill children is to have command of empirically supported psychological and behavioral treatments, integrate them with pharmacologic treatment, and understand the "myths" (71) that needlessly limit them, especially that the need for psychological intervention implies psychopathology.

Historically, empirical support for psychological/behavioral pediatric pain management modalities has been strongest for medical procedures and headache (71). Progressive muscle relaxation, for example, first described by Jacobson (72), in which serial muscle groups are first tensed then relaxed, has demonstrated efficacy in treating pediatric medical procedure pain (73). Patients and parents typically like learning it, and it has no adverse effects, though muscle groups that have been the focus of tissue damage and pain should be avoided. Innovative clinical trials in adults show that training partners in such skills as muscle relaxation has both analgesic efficacy for the patient and enhances a sense of self-efficacy in the partner. Clinical experience suggests similar effects in pediatric pain management where the "partner" is a parent (74,75). Jay et al. (76), using a controlled repeated-measures counterbalanced design, studied a package of cognitive-behavioral (CB) interventions including guided imagery, distraction, and deep breathing in 56 children with leukemia between ages 3½ and 13 years undergoing bone marrow aspiration. Compared to the control condition of 30-minute preprocedure cartoon watching, children in the CB group exhibited significantly less behavioral distress, self-reported pain, and lower heart rate during the procedure. Kuttner and Solomon (77) reviewed the evidence for hypnosis in treating pediatric pain and suggest benefit in children as young as age 3 years (78). More recent reviews (63) cite increasingly robust, empirical support for the use of a spectrum of nonpharmacologic approaches to pediatric pain management including CB (79), guided imagery (80), hypnosis (81), biofeedback (82), and complementary-alternative approaches (83). Many of these more recent studies are not specific to palliative care populations; hopefully, these will be forthcoming. Encouragingly, clinical practice guidelines specific to particular pediatric medical disorders are starting to appear, such as a recently published palliative care curriculum for providers of patients with cystic fibrosis (84). The need to equip physicians-in-training with the requisite skills in pain management is exemplified by an Internet-based pediatric pain management module for medical students (85). Astute clinical judgment, with support in the literature (86), dictates that clinicians become skilled in integrated approaches to pediatric pain management combining pharmacologic and nonpharmacologic methods.

In summary, appropriate use of empirically validated pediatric pain assessment and management tools both pharmacologic and psychological requires that they be embedded "in good clinical pain practice" (71), including the principles that pain is inherently subjective and the child's report of it should be taken at face value; that pediatric pain should be measured and monitored over time; that sick children should be told, in developmentally appropriate terms, what is going to happen to them; and that parents should accompany their children undergoing medical procedures. Dyspnea, somnolence, nausea, and constipation, among other symptoms, must also consistently be addressed to ensure optimal quality of life even at the end of life.

ROLE OF THE CHILD PSYCHIATRIST

Pediatric palliative medicine and PPC clinical services in children's hospitals have undergone explosive growth since the previous edition of this text was published. Feudtner et al.'s recent survey found that from 1997 to 2004, 15 new PPC programs were established in U.S. children's hospitals compared to 52 new programs from 2005 to 2012 (87). Among 162 hospitals responding to the survey, 69% had PPC services. While formal inclusion and funding for child psychiatrists on palliative care teams varies considerably from center to center, Buxton (43) has argued persuasively for the unique contribution child psychiatrists can make to PPC:

> "Because child and adolescent psychiatrists have medical training, they can incorporate the complex biopsychosocial picture of this severely ill population into their diagnostic evaluations … and … their medical understanding of prognostication can help provide more complete psychosocial interventions and treatment recommendations. Without this expertise palliative care providers can misinterpret behaviors and lose opportunities to treat important elements of suffering."

Child psychiatrists' developmental perspective with their understanding that medically ill hospitalized children may regress is critical. Buxton gives the example of an overwhelmed, regressed pre-teen whose pain might better be assessed using a face-based scale rather than VAS; whereas in other patients, cognitive development of concepts of death and dying in children with life-threatening illness may accelerate relative to their healthy-age peers such that children younger than one might expect may want and are able to participate actively in stating their preferences in making advance care planning decisions (43).

Importantly, recent work by Muriel and colleagues (88) presents for the first time a model for the integration, conceptually and in clinical practice, of child psychiatry and palliative care.

Anxiety and Depression

Prevalence

Medical illness is a risk factor for psychiatric comorbidity, particularly anxiety (89) and depression. Anxiety disorders are the most prevalent of all psychiatric disorders of childhood to begin with, with an estimated lifetime prevalence of 15 to 20% (90). Prevalence rises to 20% to 35% in medically ill children (91). Point prevalence of anxiety of 14.3% in children with cancer and up to 63% of children with epilepsy have been reported (92,93). Anxiety symptoms in children with diabetes have been reported in one study to last up to 10 years after diagnosis (94).

While data vary, depression also appears to be more prevalent in medically ill children, as might be expected in a population stressed by life-threat, separation, prognostic uncertainty, and pain. Depression prevalence has been reported to be two to three times greater in children with diabetes than in the general population (95), 16.3% vs 8.6% in youths with asthma (96) and five times the rate in the general pediatric population in children with complex partial or absence epilepsy (93). Atypical clinical presentations in child and adolescent depression relative to adults, important distinctions to be made between depression and end-of-life "existential crises," and the major contribution of intractable pain to mood must all be carefully considered by the child psychiatrist in responding to consultations from pediatric teams to evaluate depression.

Risk of completed suicide in medically ill children has not been systematically compared to that in the general pediatric population. On the other hand, suicidal ideation is reportedly increased in children with epilepsy (93), and adult survivors of childhood cancer (97). No currently validated screening tools for suicidality in medically ill children exist, but thorough, nuanced clinical assessment must be regularly performed. One of us (JG) has treated an adolescent with end-stage liver disease, after two suicide attempts, who went on to liver transplantation after successful treatment for depression, illustrating that treatable psychiatric disorders need not exclude terminally ill pediatric patients from life-saving medical interventions.

Intervention

While the efficacy of behavioral and cognitive approaches to mitigating distress associated with medical procedures in children and youth is well established (98), there are few studies directed at interventions for non–procedure-related anxiety and depression specific to medically or terminally ill children. Advances in treatment for anxious and/or depressed youth in nonmedical settings, however, are relevant to pediatric medical and palliative care. The finding that inflammatory cytokines may be involved in the pathogenesis of both cancer and depression (99) suggests another mechanism whereby children with cancer might be at increased risk for mood disorders and a possible role for antidepressant use in some cases.

Clinicians should be mindful of confounding influences of serious medical illness on the diagnosis of anxiety and depression in youth. Somatic symptoms commonly associated with depression including fatigue, pain, and impaired appetite and sleep are so often caused by the underlying medical illness itself that cognitive symptoms of depression (guilt, feeling like a burden, and hopelessness) are widely considered to be much more useful in medical settings.

De Jong and Fombonne (100) published case reports of four prepubertal children with cancer and "DSM-IV depressive disorder" treated in open-label fashion with

citalopram 10 mg. Using child and parent short forms of the Moods and Feelings Questionnaire (SMFQ) and the Hamilton Rating Scale for Depression (HAM-D), the authors report statistically significant mean reductions in depression severity for all three measures at week 12, with initial responses as early as week 2. An earlier pilot study of fluvoxamine in this population came to similar conclusions (92). In nonmedically ill children, the seminal Treatment of Adolescent Depression study (TADS) provides compelling evidence for the tolerability and efficacy of fluoxetine and cognitive-behavior therapy in combination in the treatment of adolescent depression (101). Choice of selective serotonin reuptake inhibitor (SSRI) in medically ill children and adolescents should be guided by relative risk of drug/drug interaction via CY P450, and elimination half-life, for both of which drugs such as escitalopram and citalopram may be preferable to others, particularly fluoxetine. Broad consensus that benzodiazepines can be associated with disinhibition, confusion and worsening of delirium, and antihistamines with cognitive and behavioral impairment due to anticholinergic effects, make these drug classes largely untenable in a medically ill pediatric population. Nonpharmacologic interventions for anxiety and depression in youth with life-threatening illness including expressive psychotherapy, narrative writing and an array of other techniques are central to the treatment of anxious or depressed medically ill youth, and are often first-line interventions prior to consideration of pharmacotherapy, for which the reader is referred to the recent review by Pao and Wiener (91).

SUMMARY

The prevalence of anxiety and depression in medically ill youth, and emerging data documenting the safety and efficacy of both pharmacologic and nonpharmacologic intervention strategies, highlight the central roles to be played by child and adolescent psychiatrists and allied mental health professionals in the comprehensive care of youth with life-threatening illness. Going forward, child psychiatrists will be increasingly essential members of PPC teams, as novel pharmacologic approaches to pain management and intractable depression with such novel agents as ketamine are studied and introduced, and with increasing recognition of the prevalence of and emerging assessment and treatment guidelines for delirium in seriously ill children. Child and adolescent psychiatrists' unique background as physician specialists in child development, family systems, psychodynamics, neurobiology, and psychopharmacology make a compelling case for their role in the growing specialty of pediatric palliative medicine.

BEREAVEMENT

Loss of a Child

Potential Risk Factors

Rando (102) identifies several characteristics of the loss or the mourner that increase the risk of a complicated mourning process for adults. Several factors relate to the nature of the death: sudden, unexpected death, especially when traumatic, violent, mutilating, or random; death resulting from an overly lengthy illness; death of a child; and death the mourner perceives as preventable. If the premorbid relationship with the deceased was marked by anger, ambivalence, or excessive dependence or the mourner has unaccommodated losses or stressors or mental illness, then there is also an increased risk of a complicated mourning process. In addition, complicated mourning is increased if the grief is "disenfranchised" such that the mourner does not perceive adequate social support for grieving because of invalidation of the loss (e.g., early pregnancy losses which are often not met with much overt social support) or the relationship (e.g., death of an ex-spouse).

Anticipatory grieving allows parents and others to experience graduated feelings of grief, while being reassured by the child's continued presence when such feelings become overwhelming. In this manner, anticipatory grieving may allow some of the "work" of grieving to be completed prior to the child's death. Unfortunately, family members (and hospital staff) often engage in anticipatory grieving at a different pace. At times, a parent (or often a hospital staff member) may prematurely disengage from a child who is dying and be seen by others, including the child who is dying, as abandoning the child. Often, unacceptable thoughts arise. For example, parents may find themselves wishing that the child would finally die and relieve everyone of the emotional and financial burden and suffering. Such a wish may horrify a parent and lead to the immediate mobilization of certain defense mechanisms. A common defense mechanism is that of reaction formation whereby the parent becomes extra protective in caring for the dying child. The parent also may feel guilty and express his or her guilt (and anxiety) by asking repetitive questions that require tactful answers. As a chronically ill child nears death, the parents may be filled with remorse and may experience a resurgence of love. Rarely, a denial that death is imminent may remain in force. After the death of a chronically ill child, parents may feel a mixture of relief and guilt, perhaps with feelings of remorse being uppermost (103).

While it is critical to involve parents in decision-making regarding their child's treatment, the health care team should not use this as an excuse to avoid assuming the difficult responsibility of formulating treatment recommendations. In particular, when further treatment is futile and when the child is being maintained on life support, the health care team should convey to the family that the child has died and invite input from the family members about whether they would like to be present when life

support is removed and their preferences on timing, without leading them to believe they are being asked whether they believe treatment is likely be effective or whether or not they "wish to allow (their child) to die." Psychiatrists can also guide the medical team on how best to notify members of the family of a child's death and, especially when children are involved, participate in the process as appropriate (103).

Funeral Attendance

Parents should be provided information about the potential benefits for grieving children of attending funerals and participating in other observances and offered advice on how to provide support to children in these settings. Based on clinical experience, it has been shown to be helpful to advise family members to appoint someone, preferably who is not directly impacted by the death, that understands children's developmental needs and that the child knows and trusts to explain in simple terms what should be expected during the funeral or other ritual, to invite the child to participate to the level that he or she is comfortable, and to accompany the child throughout the event(s). This adult can then monitor the child's reactions and allow the child to leave the ceremony whenever desired. Children often can use the funeral rite in the same way adults do, especially if they have adults in attendance who can help them understand their feelings and describe what is taking place. Children who do not wish to attend the funeral should not be made to do so or to feel guilty. Rather, arrangements should be made for them to be in the company of an understanding adult during the time of the funeral. Older children should be encouraged to participate in the rites and rituals with the adults because these practices usually help them to deal with the reality of death and to access comfort and support from family members and friends. If older children choose not to attend the funeral, the reason for the choice should be explored, but if they continue to feel that they do not want to attend, this wish should be respected. Children should not be forced or coerced to participate directly in any portion of the ceremony that they find distressing, such as throwing dirt on the casket or kissing or touching the body of the deceased (16,104).

Advance Care Planning

As noted, comprehensive care of children with life-threatening illness is not limited to dying children. Whether the ultimate outcome is cure, chronic illness, or death, early intervention by the palliative medicine team is crucial: "Until we define the palliative medicine clientele as all children who have a life-limiting condition, even while they are receiving the most aggressive curative therapy possible, we will remain in the untenable position we are in: Palliative medicine teams are allowed in

the door for children only when children are very close to death, far too late for the team to forge relationships" (105). Moreover, legal and ethical tensions and uncertainties often complicate end-of-life decision-making and take time to be resolved. Psychiatrists and ethicists may recognize the appropriateness of a competent adolescent to decline aggressive treatment, for example, but state laws may forbid it (2). Himelstein outlines four components to advance planning: (1) identification of the decision-makers; (2) clarification of patient and parents' understanding of the illness and prognosis; (3) establishment of care goals: curative, uncertain, or comfort care; and (4) joint decision-making regarding use or nonuse of life-sustaining medical interventions such as mechanical ventilation, intravenous hydration or phase I chemotherapy (2). Clearly, decisions of this breadth and depth take time. Ideally, palliative care teams become involved early as partners of the primary team: "Palliative care teams work alongside of, not instead of, the primary team. Rather than taking over, they complement that team's efforts. They ease some of the burden of caring for and communicating with the family when complex medical and psychosocial decisions must be made" (105). Advance care planning with adolescents and young adults has been growing in recognition over the past decade including randomized controlled trials of family centered advance care planning in youth and their families with HIV/AIDS (106) and cancer (107). A systematic review has been reported (108). To date only one developmentally appropriate advance care planning guide, *Voicing My Choices,* a seminal collaboration of the National Institute of Mental Health and National Cancer Institute, has been created specifically for adolescents and young adults (109,110), showing great promise in empowering patients to systematically and specifically articulate their uniquely personal wishes regarding end-of-life care.

Special Situations

Parents and Siblings

Parents' response to the death of a child has been addressed in several studies (111). In a study of 21,062 Danish parents with a child who died, mortality from "natural" (cancer, cardiovascular, digestive) and "unnatural" (motor vehicle accidents and suicide) causes was statistically significantly higher 10 to 18 years after childhood death than in control parents who had not lost a child (112). "Persistent Complex Bereavement Disorder" is classified in DSM-5 as a "condition for further study," not a psychiatric disorder per se, though clinical resemblance to major depressive disorder is common (113). Purported differences in symptom expression and impairment in "normal" and "complicated" grief may not be robust (114). Siblings also require clinical attention (115,116). Active outreach to siblings is important prior and subsequent to a child's death; recent clinical guidance from the AAP

provides detailed practical advice on how such support can be provided to grieving children and families within a pediatric medical home setting (117). In particular, the impact on older children and adolescents of sibling death is often underappreciated. Parents who are themselves mourning and feeling overwhelmed may be reluctant to appreciate the suffering of the siblings and may in fact turn to them for their own support. It is vital for the medical team, whether hospital-, hospice- or outpatient-based, to provide systematic, clinically sophisticated support and intervention either from a member of the palliative care team or through referrals to community-based psychological, pediatric, school-based (16,30,118) and if appropriate, religious resources. Critical to this process is the palliative care team's active follow-up contact with the family after the child's death.

The psychiatrist can also work with the child's school to offer advice and assistance to peers and school staff after the time of death and to better equip classroom teachers and other school professionals to support grieving siblings (16). A recent survey of educators showed that classroom teachers are well aware of the importance of providing bereavement support to grieving students, but only 7% had ever received any training on this topic and felt that this lack of training was the primary barrier that prevented them from reaching out to their students to offer support. The Coalition to Support Grieving Students, that includes 10 of the major professional associations and unions representing educators, school administrators (including both principals and superintendents), school counselors, nurses, psychologists, and social workers, has recently produced a wide variety of video-based and print materials to address this need, which is freely available at www.grievingstudents.org.

Child's Loss of a Parent

Four percent of children will experience the death of a parent before their 15th birthday (14). Since adults as well as children with life-limiting illness are living longer, needed attention is being paid to the psychosocial needs of these children (117). After a review of the literature on bereavement in childhood, the Institute of Medicine (119) summarized the factors that are associated with an increased risk of psychological morbidity for children after the death of a parent or sibling:

1. Loss in a child younger than 5 years of age, or during early adolescence
2. Loss of a mother for girls younger than 11 years of age, and loss of a father for adolescent boys
3. Premorbid psychological difficulties in the child or lack of prior knowledge about death
4. When the relationship with the deceased had been conflicted or when the parent remarries and there is a poor relationship between the child and the stepparent
5. When the surviving parent is psychologically vulnerable and excessively

dependent on the child, or the environment is unstable and inconsistent

6. When there is a lack of adequate family or community supports, or when the surviving parent is unable to access available supports
7. When the death was unanticipated or the result of suicide or homicide

Providers

Hospital staff members also experience anxiety in the presence of a dying child or a grieving parent, and they may tend at times to deal with that anxiety by withdrawal and a conspiracy of silence. These reactions may impair their ability to give the dying child and his or her family the best care possible.

The death of a patient is one of the most stressful personal and professional experiences faced by health care providers. Clinicians need to understand their personal feelings about death in order to be effective in providing support to children who have experienced the death of a loved one, or who are faced with their own impending death. Often this will involve on the part of the physician some introspection about prior personal losses. But perhaps most important, health care providers should remain conscious of the impact that helping children who are dying or grieving has on both their professional and personal lives, and they should seek and establish means of meeting their own personal needs regarding bereavement (117).

Jellinek (120), Frader (121), and others have addressed the special challenges to physicians and allied professionals in the care of seriously ill children, particularly physicians in training. Biologic and psychological patient outcomes, from glucose homeostasis to pain control, are strongly associated with the quality of provider–patient communication. Models for training physicians and allied professionals in patient-centered communication exist, have been evaluated, and are effective (122). Operationalizing provider communications training is challenging, but possible, and is now required in residency training programs by ACGME mandate. An important review on this topic has recently been published (123).

SUMMARY: PALLIATIVE CARE, RELATIONSHIPS, AND MEDICAL EDUCATION

Bowlby's marriage of ethology, neuroscience, and psychoanalysis gave child psychiatry a language for understanding and investigating attachment, separation, and loss (124). This biologic substrate, mediating and mediated by experience, is brought sharply into focus by life-threatening illness. Loss is universal, but the loss of a child —jarring, unexpected, and unnatural—is as severe a stress as the child or the child's parents and siblings can experience. Fortunately, clinical studies demonstrate that gravely ill children and their parents may both endure and even grow under the right

circumstances at least some of the time. Hinds et al. (125) evaluated 10- to 20-year olds with advanced cancer within 7 days of one of three decisions: (1) whether to enroll in a phase I clinical trial; (2) whether to support a do not resuscitate order; or (3) whether to limit care to comfort measures and forgo life sustaining treatment. Both children and adolescents in the study understood they were making end-of-life decisions, and strikingly, expressed altruistic motives—the wish to help others unknown to them—in their decision-making, for example, participation in a phase I trial knowing it would not be lifesaving for them but could be for others. Similarly, Mack et al. (126) found in an interview study of parents whose children died of cancer that parent ratings of the quality of the child's care was directly proportional to the quality of physician communication. Parent-reported attributes of "quality communication" by physicians included providing clear information about what to expect at the end of life, conveying bad news sensitively, and including the child patient in discussion when appropriate.

Pediatric palliative medicine is an established, growing multidisciplinary subspecialty. Child and adolescent psychiatrists and allied professionals are uniquely qualified to play key roles on palliative care teams with their special expertise in addressing issues of attachment, separation, and loss universally experienced. Historically, there has been little attention in medical school curricula to training students in the competencies necessary to provide quality communication and caregiving to life-threatened children and their families; as noted, medical educators are recognizing and remediating this. As of this writing, Northwestern and Harvard Medical Schools offer educational programs on palliative care, including pediatrics (127,128). Such efforts must be encouraged, expanded, and their impact on the quality of medical education and clinical care systematically evaluated.

ACKNOWLEDGMENT

The authors wish to acknowledge Melvin Lewis, MB, BS, FRCPsych, DCH for his important contributions to earlier editions of this chapter.

7.3 Schools

CHAPTER 7.3 ■ SCHOOL CONSULTATION

JEFF Q. BOSTIC AND SHARON A. HOOVER

Schools are among the most valuable sites for child psychiatrists to promote mental health. Almost all children attend schools, where many of their unique needs can be addressed daily by committed professional school staff. Symptoms of psychopathology usually manifest across home and school settings, yet the range of interventions is often much wider in schools where classrooms, school staff, and instructional/behavioral approaches to the child can be configured to optimize the fit between child and school.

As psychiatric hospitalization continues to give way to treatment efforts in more naturalistic settings, schools have become primary venues for management of mental health by child psychiatrists. At one end of the spectrum, the *school psychiatrist* provides *direct* treatment to students or staff. This direct treatment usually occurs on-site at the school and may include face-to-face evaluations of students or staff, individual or group therapy, or medication management. This allows teachers and staff to access the child psychiatrist for specific mental health issues, and allows the child psychiatrist to factor in the school's resources and philosophy in devising interventions. At the other end of the spectrum, the *school consultant* advises school staff, providing *indirect* services to students by assisting school personnel. The consultant may meet with administrators concerned about how best to respond to the death of a teacher, or to provide recommendations to help teachers work with students who have depression, attention or disruptive behavior problems, autism, or other special needs. Child psychiatrists often blend these roles, sometimes treating and advocating for a patient, and sometimes consulting various school staff around complex problems (1).

Child psychiatrists will continue to become essential partners in schooling children, not just those children identified with psychopathology, but all children. The mental health consultant is often able to benefit many more children than would be possible through providing direct service on-site at a school. Of those children with a diagnosable mental health disorder, less than half receive treatment, and over 75% receive this treatment at schools as attrition rates remain high for mental health treatment outside of schools (2,3). Proactive efforts to prevent and diminish psychopathology will continue to supplant reactive, treatment-only approaches employed only in response to crises or emergence of psychiatric disorders. Child psychiatrists will continue to provide input on specific emotional disabilities, and increasingly promote mental health for all students, providing input on programs and principles found effective for everything from combating depression to decreasing bullying, and by working directly with educators to adapt effective treatments to diverse school environments (4).

EMERGENCE OF SCHOOL MENTAL HEALTH SERVICES

Mental health entwined with schools over the last half of the 20th century following significant social movements. After hundreds of thousands of refugee students were displaced at the end of World War II, Gerald Caplan used school-based interventions to assist teachers working with these students. The civil rights movement in the 1960s brought about federal education rights legislation. No longer could schools require students with disabilities to fit into their existing programs. Systematic identification of students with emotional and behavioral disabilities began, accompanied by a need for clinical advice about assessing and treating these students in the least restrictive school settings. Increased social change in the late 1960s and wider recognition of problem behaviors among students, such as substance abuse, unprotected sexual intercourse, and more recently, bullying and school violence, caused schools to turn to mental health clinicians for advice. This increased awareness of student emotional and behavioral health problems was accompanied by language and policy changes, including Eli Bower's research and conceptualization of the "emotionally disturbed" student, which served as a foundation for the initial version of the **Education for Handicapped Children Act** of 1977 (5). This legislation, along with Bower's research and advocacy, are recognized as critical to the establishment of schools as a critical venue for supporting the emotional and behavioral needs of students in order to improve their academic success.

The decrease in the 1990s in psychiatric hospitalizations and residential placements, coupled with the lack of access to mental health care among those most in need, resulted in proliferation of school-based mental health treatment, and delivery of psychiatric services within schools (6). As evidenced in the Dryfoos' (1994) book, *Full Service Schools: A Revolution in Health and Social Services for Children, Youth, and Families,* schools were increasingly recognized as a place where all students, especially students with psychological problems, could receive comprehensive services.

The No Child Left Behind and subsequent legislation required intervention earlier for those students not progressing as expected. The President's New Freedom Commission report of 2003, *Achieving the Promise: Transforming Mental Health Care in America,* emphasized the impacts of mental health on learning and social–emotional development. This report provided recommendations to address gaps in the provision of mental health services to youth, including the expansion of school mental health programs. In 2004, the **Garrett Lee Smith Memorial Act** (P.L. 108–355, October 2004) became the first federal legislation in the United States to provide specific funding for youth suicide prevention and early intervention programs, as well as interventions and treatments for mental and behavioral health problems that can lead to suicide in young people. Most recently, the **Every Student Succeeds Act**, enacted December 2015, requires that states and local education

authorities work with diverse stakeholders to develop comprehensive interventions for students at risk of school failure, and that they articulate and measure efforts to improve school climate, including supporting the emotional wellness of students. Psychiatrists and mental health clinicians have become partners with education professionals to respond to traumatic events at schools, such as natural disasters (e.g., surrounding hurricanes or tornados), or catastrophic human events such as murders or war. Increased proactive, resilience-building for students, facing seemingly ever-increasing stress loads, have expanded the range of mental health efforts at school, including social–emotional learning curricula, mindfulness, and executive skill coaching. This chronology, and some important lessons learned over time, are provided in Table 7.3.1.

TABLE 7.3.1

MAJOR EVENTS IN PSYCHIATRIC CONSULTATION TO SCHOOLS

Social Event	Mental Health Impacts on Schools	Child Psychiatry Response	Lessons Learned
Aftermath of WWII	Displaced orphan students required emotional support to contend with school	Mental health providers worked with educators to manage displaced students	Life events require mindful planning to promote mental health and resiliency in children
Civil rights movement	Equality for all, including those with disabilities, required schools to accept and respond to diverse students	Child psychiatrists identified psychiatric disorders that schools considered as possible educational disabilities	(1) Psychiatric disorders did not necessarily “fit” educational disability categories (2) No consensual or empirical school interventions for identified disorders/disabilities existed
Social change and problem behaviors	Problematic behaviors, and their negative impact on schooling, increasingly evident in the classroom	Child psychiatrists provided input on lifestyle variables influencing quality of life	(1) Little empirical evidence supported child psychiatry recommendations (2) Efforts to identify the prevalence of substance abuse and other problem behaviors helped illuminate mental health issues
Decrease in psychiatric hospitalization	Students managed in non-school environments returned to schools to receive an education appropriate for them, given complex needs	Child psychiatrists focused on discharge planning to provide outpatient treatment, including in school settings	Psychiatrists and educators partnered, by necessity, to address mental health issues impacting children in daily environments
Impacts of	Students with	Embrace broader “RtI”	Proactive efforts to screen,

mental health on learning	diverse mental health difficulties have similarly diverse struggles at school as well as impact classroom instruction	(Response to Intervention) approaches to identify and respond varying degrees and impacts of psychopathology at school	recognize and respond to students can enhance school achievement
Resilience to traumatic events at schools	Traumatic events at school illuminated the importance of early detection and intervention for all students	Assist in the development of more sophisticated screening and evidence-based interventions for students at risk	Mental health supports can accelerate recovery from traumatic events
Emphasis on social emotional learning	Increased evidence for the positive impact of universal social–emotional learning on student psychosocial and academic functioning	Consultation on selection of universal mental health promotion and prevention programming and consideration for how brain science can help inform and evaluate this programming	Psychiatrists' knowledge of brain science and etiology and development of psychopathology can support the shift from treatment-only approaches to promotion/prevention activities, and cultivating social skills

MODELS OF CONSULTATION

Multiple models of psychiatric consultation to schools have emerged, including the mental health model, the behavioral model, and the organizational model. These models are summarized in Table 7.3.2, as well as differences in their approach to the same problems. Regardless of the specific model, the child psychiatrist role appears broadening as collaborator, expert consultant, and partner in prevention, early intervention, and service delivery efforts (7).

MENTAL HEALTH CONSULTATION

Mental health consultation (MHC) (8) stresses that the consultant's goals are both to be helpful with the problem at hand and also to provide the consultee new knowledge and skills to handle similar problems in the future. The focus of mental health consultation is usually to understand how a student's mental health functioning impacts his or her school success, and to offer recommendations about school interventions tailored to meet the mental health needs of the student. This type of consultation is frequently "indirect," as the consultant may hear about a troublesome student from a parent or staff, and make recommendations to these staff, sometimes without ever seeing the student. The consultant may be paid by the school district or other entity (e.g., student insurance via a community behavioral health provider), and

the consultee is free to follow (or not) the consultant's recommendations.

Behavioral Consultation

Behavioral consultants attempt to change the behavior of teachers and students by focusing on: (a) problem identification, (b) problem analysis, (c) plan implementation, and (d) problem evaluation. During the *problem identification* stage, the consultant and teacher identify a specific problem to address. Usually, a "problem" occurs when the student's observed behavior is not what is desired and expected by the teacher or other school personnel. When a discrepancy exists between current and desired behavior, the consultant and teacher establish goals for the resolution of the problem, formulating the problem in behavioral terms. During *problem analysis,* the consultant and the school staff generate hypotheses about factors that influence the behavior and design a plan to solve the problem. During *plan implementation,* the consultant and school staff enact the plan and also collect data to measure how the problem behavior changes following implementation. During *program evaluation,* the consultant and school staff examine whether the goals have been attained, if new problems have arisen, and how the plan should be continued, modified, or phased out (9–11).

Behavioral consultation has advanced through the *collaborative problem-solving* model described by Greene and Ablon (12). This behavioral approach diverges from pre-existing behavioral models by suggesting that students often lack a repertoire of other behaviors to employ when in complex situations, and so revert, almost inflexibly, to primitive or aggressive behaviors in such circumstances. Problem behaviors require adults (teachers or parents) to respond to the "message" attempted by the student's behavior, rather than efforts to immediately stop the behavior or to ignore or tolerate it. Rather than conventional reinforcement when desirable behaviors spontaneously emerge, or punishment when misbehaviors occur, desirable behaviors have to be identified, agreed-upon by the student and teacher, and practiced so that they become familiar parts of the student's repertoire.

Organizational Consultation

Organizational consultation focuses on schools as systems and seeks to facilitate improvement in school functioning through the application of behavioral science concepts and the involvement of usually multiple system members (e.g., administrators and teachers) in the process of organizational change. Difficulties may emerge because of mismatches between the students and requirements of the educational system. Systemic problems such as communication breakdowns and ambiguity about responsibilities can cause anxiety and frustration among school staff, and impact student progress and behavior. Individual student problems may

illuminate school system factors that contribute to the problem, and should be modified. For example, in one suburban elementary school, a large number of students were receiving office discipline referrals. Upon examination of discipline data, it was revealed that the substantial majority of referrals were coming from one out of the five fourth-grade teachers. During consultation it emerged that her referral rates increased following new policies that decreased paraprofessional support while simultaneously increasing the number of students with challenging behaviors in her classroom. In this case, focusing on school policies and practices, rather than solely on the students' individual behaviors, became a priority. Models addressing low-achieving schools, such as the Comer School Development Program precipitated school restructuring and change in school culture and climate, positively impacting student self-esteem, motivation, and achievement (13). The 2015 reauthorization of the **Elementary and Secondary Schools Act** requires states to measure and address organizational factors that may impact student mental health, including school climate, providing increased opportunities for child psychiatry consultants to consider organizational factors that could support students' school success.

THE ROLES OF SCHOOL STAFF WITHIN SCHOOL CONSULTATION

Most commonly, child psychiatrists interact with schools to coordinate treatment for their patients. Whether acting as a school consultant, or communicating with a school to coordinate patient treatment, establishing an effective partnering relationship is critical, particularly if the school is asked to make accommodations for this student. Child psychiatrists often need to be aware of the staff options at a patient's school so that helpful school staff can be accessed and empowered to address the patient's needs.

TABLE 7.3.2

CONTEMPORARY MODELS OF SCHOOL CONSULTATION

	Consultation Model		
Aspect of the Consultation	**Mental Health Consultation**	**Behavioral Consultation**	**Organizational Consultation**
Initial focus	How mental health impacts student progress	Problematic behaviors exhibited by students/staff	How school contributes to problem
How information is obtained from consultee	Clinical interview with student/parents, review of school data, psychological testing	Direct observation in classroom, counting frequency, length of specified behaviors	Review of school philosophy, curriculum, instructional philosophy, administrative procedures for problem class or group
Objective	Help consultee identify	Help consultee measure	Help consultee refine

	strategies to address mental health problems interfering with school success and strengthen psychological assets	problem behaviors, alter and shape student responses leading to problem behaviors	organizational configuration and goals to diminish circumstances
Evaluation of model	Do identified intervention strategies improve student mental health functioning? Does student's school performance improve?	Do specific problem behaviors diminish in frequency/intensity? What does "data collection" reveal?	Does this specific problem illuminate larger problems in policy impacting multiple students? Does the proposed solution benefit everyone?
Example case (17-year-old student who does not attend regularly the year after becoming a teen parent)	Consultee identifies depressive symptoms that occurred postpregnancy, constructs a plan with the student, teachers and family to re-engage student in pleasurable activities, teach cognitive coping, and monitor mood	Consultee keeps track of days/times missed, addresses directly with student, and they construct plan for student to be there on time by having others care for child on certain days; they measure success of plan, and revise as needed	Consultee identifies well-intended but misattuned policies for attendance for current school population, and provide alternative schedule for students with children, course credit that can be completed at home, and course credit shifted to allow parenting study/work to count toward graduation

Roles of School Personnel

As the demands on schools have intensified, staff roles have changed, such that consultants must have realistic expectations about who can perform specific interventions with students. The consultee may be anyone within the school hierarchy, and the consultant must address these needs while being mindful of how the consultation will impact everyone else within the system. The consultant must also consider who is in a position to implement recommendations when providing consultation.

Teachers remain the front-line staff most involved with students. Elementary teachers usually have approximately 25 students for 6 hours each day. By middle school, teachers usually teach in a specific content area, providing instruction to approximately 150 different students each day. *Special education teachers* are credentialed to provide alternative instruction to smaller groups of students with learning disabilities, including dyslexia, nonverbal learning disorders, or emotional disorders that interfere with learning. For students to receive instruction from special education teachers, they must have an individualized education program (IEP). *Aides* often do not possess a 4-year college degree or teacher certification, but may assist a classroom teacher, or work directly with a specific student.

School psychologists are either employed by the school or have a contract with the school to administer and interpret psychological testing and help construct IEPs

for students to address their specific learning difficulties. They may also provide individual and group therapy to students. *School counselors* (formerly referred to as guidance counselors) sometimes provide psychotherapy to students, although their primary role in secondary schools is often to assist students in college or vocational planning and academic planning, including class selection. *School adjustment counselors and/or social workers* have been added to school staffs in many locations, where their primary role is to provide psychosocial interventions to students, and sometimes their families.

School nurses address acute health care needs of students, and administer medications to students; however, school nurses sometimes travel between several schools each day so that supporting students' complex or frequent medication regimens become difficult.

Occupational therapists work with students individually or in small groups to help students with basic activities of daily living, and alternative strategies for students who have sensory integration issues to help them learn to cope with various stimuli. *Speech–language therapists* meet with students who have communication and social skills difficulties individually and in small groups.

School administrators liaison between the school and the community. *Principals* manage all services (from teaching to custodial) within their school building, and report to the superintendent. The *superintendent* guides educational activities among all the schools within a school district, and reports to an elected *school board* in public schools, or an appointed board in private, parochial, or charter schools.

ESTABLISHING A RELATIONSHIP WITH A SCHOOL

Schools today face great demands to impart knowledge, to prepare students vocationally, to socialize children to interact with others effectively, and to protect their health and safety. These varied, often competing, agendas impact every intervention proposed by the child psychiatrist, regardless of the child psychiatrist's role "identified" by the school. Moreover, public, private, parochial, and charter schools not only vary widely in their priorities, but also in their system hierarchy and their accountability to the community. Familiarity with each individual school, its priorities, and its staff is a prerequisite to any meaningful consultation.

Evaluating a School

When the child psychiatrist has the opportunity to visit a school, a framework for evaluating the school can help discern the fit between that school and a particular student, as well as better match interventions to the culture of that school. Table 7.3.3 provides a sample approach child psychiatrists can use when entering a school. Awareness of the general reaction the consultant has to the school and its staff helps

clarify the likely fit between a school and an identified student. Depending on the needs of the student, the child psychiatrist may employ relevant questions from Box 7.3.1.

TABLE 7.3.3

FRAMEWORK FOR EVALUATING A SCHOOL

School Component	What to Observe	Potential Questions for Staff
School building	Safety/security: Does the building appear safe? Is the building comfortable (temperature, chairs beyond desks, lighting, noisy)? Does the building value students (student art on the walls, recognition of student achievements, evidence of parent–teacher alliance)? Is this a place a child would want to be in?	How does one enter/exit the building? Where do students go if they are having a hard time? Where are students' classwork or projects kept or displayed? What happens after school is over? Do students stay in the building before or after school?
Classrooms	What do classrooms look like? How big is the room? How many students are in this room, and how many adults? How many learning areas are there, and are they separated so children can be in a quiet place within the classroom? How stimulating (visual, auditory, tactile) is this classroom, and do the students appear over/understimulated?	What's the average number of students in each classroom? How are teachers encouraged to set up their classroom? If a student is having a hard time in the classroom, where does he/she go? How did you (teacher) decide what to put up in your classroom?
School atmosphere	How is a stranger greeted? Does the school seem organized for students or for staff? Do most students appear engaged with instruction (are students within classrooms, alert, attentive, answering/asking questions?)? How do students and staff interact (smiling, directives, calm, tense)? Do children thrive here?	Whom should I meet when I enter the building? How do students move between classes/to lunch/recess? What do students do when they've finished classroom assignments? What do staff expect from students here? What do staff most worry about here regarding students?
School staff		
Administrators	Are administrators present/accessible? What kind of tone/impression does the administrator convey? Do staff appear comfortable around the administrator? Who does this administrator best serve (students, teachers, parents, other administrators)? What led to this administrator being selected for this building (student needs, up/down move for this administrator)?	What kind of interactions does the administrator have with students (discipline, earned reward time, common interests discussed in halls/lunch)? What is the administrator's priority in this building? What do staff seek from the administrator (support, camaraderie, ideas, discipline, avoidance)?
Teachers	Do teachers want to be in this school (eager to be with students or staff)? Do teachers stay in this building? How do teachers engage students (time to	How many teachers left this building last year? Average over the last several (5) yrs? What is the student: teacher ratio?

	work, demonstrate content, model enthusiasm, surprise students)? How often do teachers alter the instructional approach (every 10 min, something different [lecture, student reading, class discussion], or employ different modalities [visual, auditory, tactile]) employed during instruction?	What's the average length of time teachers have been in this district/building? How many teachers here have advanced (masters, doctoral) degrees? What kind of teachers do best in this school (independent, orderly, collaborative, creative)?
Special staff	Are other school staff present? How do teachers and other school staff interact (take student out, co-teach, friendly/tense)? How do teachers describe other staff (particularly contributions of special educators)?	What kind of special educational staff work here? How often are they in this building (always, weekly)? What kind of other teachers are in the classroom (parent aides, "paraprofessionals" aides)? Do they work with particular students, with everyone in the classroom…?
Support staff	Are support staff friendly? Do they appear open about discussing the school and students? Do support staff work well with other staff?	What kind of support staff are in this building? How long have most of them been here? How are support staff paired up with other staff?

BOX 7.3.1

School Consultation Framework

The psychiatric school consultant should consider how *micro problems can lead to macro solutions,* that is, how individual student problems can be addressed to improve circumstances for all subsequent students and staff. Five components should be considered in every consultation:

1. Who is the actual **Consultee,** and what are the *confidentiality* parameters?
2. What is the Consultation **Question,** and what is the consultee seeking and wishing will happen?
3. How is the larger **System** experiencing this problem?
4. What **Legal or Ethical Factors** should be considered?
5. How does the consultant understand this problem **Biopsychosocially**?

The Consultee and Confidentiality Parameters

The consultant must establish procedures to clarify who is appropriate to contact or to evaluate. When requested to meet with students, the consultant must obtain parental permission before interviewing any student. If parents refuse for the consultant to evaluate their child, the consultant may still observe, unobtrusively, the student, and consult the staff about their questions on how best to work with this student. Clarification of confidentiality should occur, sometimes recurrently, with staff, students, and parents. Anyone meeting with the consultant should understand how information is shared and whether written clinical information is placed in the student or personnel records.

Clarification of the Consultation Question and Needs/Wishes of the Consultee

Consultants help others define the problem and envision solutions. While consultees may ask for interventions to assist a student, sometimes they actually wish the consultant will address administrators, or recommend the student be removed from this consultee's classroom. Consultants must "read between the lines" to clarify both the consultee's overt request as well as underlying desires. The success of every consultation depends on the consultant understanding the consultee's concerns and wishes, such that both agree on the problem and on realistic goals for any intervention.

The System Reaction to the Problem

The problem will affect various school staff members differently, and each may have different goals for this consultation. Consultants should clarify who requested a consultation, who knows about the consultation, who has consented to the consultation, and who should be informed about the findings for this consultation. The more that differing goals can be aligned, the higher the probability that participants will invest in a proposed solution.

Legal and Ethical Factors

Special educational laws may provide the student different opportunities, yet families or schools may not see the applicability of such laws in a particular case. Similarly, the case may be confounded by ethical dilemmas, particularly in cases of suspected abuse. If abuse is suspected, the consultant may help staff articulate concerns to the appropriate agency, or assist parents and the school in addressing circumstances or staff perceived as abusive. In acutely dangerous situations such as suicidality or homicidality, the consultant can help consultees facilitate emergency treatment or how to warn others who may be at risk. Potential legal and ethical ramifications should be considered for every proposed intervention.

Biopsychosocial Understanding of the Problem

Child psychiatrists consider people's biologic vulnerabilities to psychopathology, their past experiences, and current family, peer, school, or other social stressors in explaining dysfunctional behaviors. These different influences may provide multiple intervention targets for a particular problem and should take into consideration existing services in the school and community. A student may need interventions biologically, psychologically, and socially, such as a referral for a medication evaluation, a behavioral plan at school and home, and connection to social groups such as sports teams, choir or band, or summer camps.

BOX 7.3.2

School consulting techniques

Ally

(1) *Validate consultees' perceptions before proposing any solutions.* Validating perceptions cultivates consultee trust that the consultant understands their predicament. If in doubt, ask questions or pose solutions as questions ("What would likely happen if we...?").

(2) *Bind anxiety.* Everything the consultant does either increases or decreases anxiety within the system. The more people who share the problem, the less anxious each individual will be. While consultants may not know the answer to various problems, thinking through how they would find an answer can diminish consultee's anxiety.

(3) *Create respect for everyone involved.* Minimizing splitting of staff, students, and parents decreases the probability that individuals will oppose an intervention. The consultant can attempt to separate personalities from the problem by focusing on terms used, by identifying the common goals between parties, and by identifying the circumstances each party uniquely faces.

Align

(4) *Find the good intent gone awry.* When students or staff act inappropriately, the consultant can back up to the good intention that motivated the person's (mis)behavior so that self-esteem, and thus willingness to attempt different behaviors, is maximized. For example, if a teacher "yells" at students, the consultant can "backtrack" to the diligent efforts by the teacher to get the student's attention and to feel responsible that the student learns the material. Then the consultant is positioned to examine alternatives (visually signal the child, use a very soft voice, etc.), which will seem less critical of the teacher's yelling.

(5) *Help others to see the child (or staff member) differently*. Maladaptive behaviors may be used to solve problems when no other solution is available (e.g., talking in class may be the only way a student "knows" to slow down instruction or to obtain positive attention from others since the student cannot garner positive attention by doing the academic task).

(6) *Connect others*.
Look for opportunities to connect others to benefit the staff or student, utilizing existing services in

the school and in the larger community.

(7) *Appeal to shared values by giving people options they cannot argue with.* Explore and identify appropriate desires of students and staff so that interventions can be provided to realize those appropriate goals. For example, identifying that a student seeks to attend college, or hold a particular job, provides a "frame" for posed interventions ("You've indicated you want to attend/work at _______, and they require you show up on time so we have to practice going to sleep at 10 pm so that you can be ready the next morning.").

Mobilize

(8) *At every opportunity, expand the consultee's skills*. Whenever possible, the consultant attempts to assist the consultee in selecting and implementing skills helpful for that situation. The consultant aspires to provide the consultee facility with multiple skills that the consultee can use subsequently independently.

(9) *Use the consultee's own words to frame interventions.* Framing interventions with terms used by the consultee, by staff, and by students, increases each person feeling heard, and improves the probability of each investing in proposed solutions.

(10) *Identify one step up from the current situation.* Consultees may need help seeing the steps in a sequence toward appropriate behavior (e.g., Cursing may be "a step up" from physically assaulting others). Even small positive changes generate momentum to achieve greater changes.

(11) *Move toward anticipating problems rather than reacting to them.* Efforts to help consultees see how problems arise, and how they might be prevented in the future can empower consultees to find and face problems early. More importantly, initial reactions may not represent optimal solutions, but instead create additional conflicts or problems.

THE SCHOOL CONSULTATION PROCESS

The goal of school consultation is to build alliances and to share information that helps the school staff recognize and resolve problems. This process can be broken down into three tasks: (1) *allying with consultees;* (2) *aligning consultee objectives; and* (3) *mobilizing consultees to follow through with interventions* (14). Allying with consultees requires the consultant to empathize with consultees and to decrease their possible resistance. In aligning consultees, the consultant reframes people's comments, behaviors, or positions to establish unifying goals attractive to all participants. Mobilizing consultees to act requires the consultant to invest the participants in solving the problem and to empower consultees with the skills to be successful with the intervention. Consulting techniques helpful in accomplishing these tasks are described in Box 7.3.2.

SPECIAL EDUCATION

Child psychiatrists often identify psychiatric disorders which require changes within the school setting for patients to benefit. The child psychiatrist is expected to identify specific disabilities (disorders) that impact a child's performance in the classroom, and to clarify changes, such as additional time for test-taking for students with attention-deficit hyperactivity disorder (ADHD), or deviations from certain readings for patients with mood disorders, or writing activities in patients with nonverbal learning disorder. Child psychiatrists may recommend services, such as social

pragmatics instruction in patients with autism, and may comment on educational settings, although child psychiatrists should not recommend specific placements for their patients. Based on services needed, the child's educational team is obligated to identify the most appropriate site for service delivery. Many options now exist for schools to educate students with psychiatric disorders, so the child psychiatrist must have some familiarity with the special education process, and the legal parameters surrounding educational planning for these students (15).

Special education refers to specialized instruction for students who cannot benefit sufficiently from traditional classroom instruction. Eventually, all students will be appreciated as unique learners, as every child, wherever on the disability spectrum, deserves specialized instruction to optimize his or her potential. Schools continue to become more sophisticated in addressing the needs of all their students, currently propelled by legal efforts to support education of each child in the United States. Legal protections have evolved beyond the equal protection clause of the 14th Amendment to the US Constitution to provide every student with a free, appropriate education. Any child who is not progressing appropriately in school is entitled to an evaluation to determine if a disability is present, whether this disability interferes with school performance, *and* whether specialized teaching and/or other supports are needed. Anyone, including the student, the student's family, school staff, or a clinician (such as a child psychiatrist) can request an evaluation for a student. This eligibility process is summarized in Figure 7.3.1.

The American with Disabilities Act and Section 504 of the Rehabilitation Act of 1973

The **Americans with Disabilities Act (ADA)** prohibits the denial of educational services, programs, or activities to students with disabilities, and prohibits discrimination against all such students once enrolled. If parents suspect their child has a disability, they may request an evaluation to determine if a disability is present and interferes with educational progress. This is usually provided in writing to the school's principal. A child with a suspected disability is usually referred to a student support team at the school to provide accommodations. *Accommodations* refer to classroom changes that help the student meet requirements, without "lowering" academic standards.

Schools may generate an accommodation plan for such a student called a *504 Plan.* These plans derive from **Section 504 of the Rehabilitation Act** (1973), which ensures that all disabled children receive a "free and appropriate public education" (FAPE) in the "least restrictive environment" (LRE). Both ADA and Section 504 are managed by the Office for Civil Rights; the focus of both is to ensure that all students have an equal opportunity to benefit from the educational opportunities available to students in a given school. ADA is broader since Section 504 only pertains to school districts that receive federal funding. Section 504 services apply to any person who has a "physical or mental impairment which substantially limits a major life activity" so schools often attempt a 504 Plan for students with disabilities minimally impacting educational progress. Students qualifying for a 504 Plan may receive special *accommodations* to help them meet educational requirements, usually within regular school classrooms.

The Individual with Disabilities Education Act

For students with more severe psychiatric disorders, additional safeguards have been provided by Public Law 94–142 (1975), revised as the **Individual with Disabilities Education Act (IDEA)**, and most recently reauthorized in 2004 (technically as the Individual with Disabilities **Improvement Act**). IDEA extended a free, appropriate public education to students with disabilities, mandating specialized instruction and related services if necessary to meet these students' unique needs. The IDEA defines "children with disabilities" to mean children with autism; deaf–blindness; deafness; emotional disturbance; hearing impairment; intellectual disability; multiple disabilities; orthopedic impairment; other health impairment (ADHD historically has been included in this category); specific learning disability; speech or language impairment; traumatic brain injury; and visual impairment including blindness. IDEA defines "emotionally disturbed" (previously called "serious emotional disturbance") as a condition having one or more of the following over a long period of time, to a

marked degree, and which adversely affect educational performance: an inability to learn that cannot be explained by intellectual, sensory, or health factors; an inability to build or maintain satisfactory interpersonal relationships with peers and teachers; inappropriate types of mood or behavior under normal circumstances; a general mood of unhappiness or depression; or a tendency to develop physical symptoms or fears associated with personal or school problems.

In addition to having a diagnosed disability, to qualify for services under IDEA, the child must require *specialized instruction* (instruction from a special education teacher) because he or she is *not* making effective progress in school (which includes social and interpersonal progress–not just academic progress). If any of the above conditions are *not* met, the child is *not* eligible for IDEA services, but may be eligible for a 504 Plan or for other services.

The evaluation for IDEA eligibility is more comprehensive than for a 504 Plan. A multidisciplinary team of school-based professionals may conduct a comprehensive individual analysis of *all* suspected areas of disability. Usual components include assessment of the student's: (1) cognitive abilities; (2) communication abilities; (3) academic performance; (4) social–emotional status; (5) medical history/health status; (6) vision–hearing screening; and (7) motor abilities. Additional components (specialized evaluations) may be added as deemed necessary, such as intelligence testing, speech–language testing, achievement testing, neuropsychological testing physical examination, occupation–physical therapy evaluations, and psychiatric assessment (4). If the parent feels the evaluation is inaccurate or would like additional input, an independent evaluation may be requested, although the school is *not* "bound" to follow recommendations from an outside evaluator (including the patient's child psychiatrist).

The IDEA provides for educational services to include disabled children under the age of 6, and when necessary, up to the student's 22nd birthday. IDEA ensures that all disabled children receive an *IEP* with parental input and consent, and includes due process guarantees if parents disagree with this IEP or with the student's placement in an alternative setting or school. The IDEA prevented "troublesome" children from being refused admittance or from being ejected from a school because the school contended that it did not offer an appropriate program; instead the school *must* provide a free, appropriate education in the least restrictive setting. IDEA goes beyond Section 504 by allowing *modifications* so that the student does not, depending on that student's disability, have to meet the same academic requirements as students in regular education. For example, just as a wheelchair-bound student would not be required to meet physical education requirements applicable to students without a disability, students with a psychiatric disability might not be required to contend with upsetting curriculum content (posttraumatic stress disorder), or complete the same amount of problems (ADHD), or participate in certain class requirements such as speaking in front of the class (social anxiety

disorder). The multidisciplinary team devises the IEP, and components of an IEP are provided in Table 7.3.4.

A. Determining Special Education Eligibility

(1) Does the child have *one or more of the following types of disability* (documented by the medical evaluation/diagnosis, educational/psychological testing, etc.)?

- Autism
- Developmental Delay
- Intellectual Disability
- Sensory-Hearing, Vision, Deafness, Blindness
- Neurologic
- Emotional
- Communication
- Specific Learning
- Other Health

(2) If one or more of these disabilities is present, is the child *making effective progress in school*? If the student is being *reevaluated* to determine if a disability is still impacting the child, would the child continue to make progress in school without the currently provided special education services?

(3) Is the lack of progress a *result of the child's disability*?

(4) Does the child *require specially designed instruction in order to make effective progress in school* or does the child require related services in order to access the general curriculum?

B. School Service Plans for Students with Psychiatric Disorders

Type of School Service Plan	District Service Plan	504 Plan	Individualized Educational Program (IEP)
Purpose	To respond quickly to mild changes in the student's life that impact learning; focus is on mild and/or brief circumstances that may impact learning	To ensure that all students have equal opportunity to learn, even if they have a disability; focus is student's opportunities as compared to other students in that school	To remediate symptoms of a student's disability; student's unique needs are the focus
Criteria to receive this plan	Student has a symptom or disorder that impacts learning	Student has an impairment that limits a major life activity, but may not require specialized instruction	Student has a disability which interferes with educational progress, and which requires specialized instruction
Who develops this plan	Teacher and administrator, usually with parental input	Teacher, administrator (often the school's designated "504 coordinator," school counselor and usually parent, student) (if appropriate)	Educational team, including staff certified in special education; may include evaluations by school psychologist, social worker; parent may bring friends, advocates, own evaluators to be part of team
What is usually provided	Changes within classroom to enable student to perform better	Changes within classroom or school building to enable student to complete curriculum expectations	Changes within classroom setting(s) to provide student different instruction, and may substantially alter what is required of student
Example of what is provided	Student is allowed to sit closer to teacher during instruction; student is met by familiar staff to decrease anxiety	Student is allowed more time to complete tests; Student may be provided device to hear better	Student may leave regular language arts class and receive specialized reading program; student may be exempted from course requirements
Which staff deliver services	Usually regular education staff	Usually regular education staff	Staff with specialized training (special education teachers, speech therapists, occupational therapists, etc.)
Where the student receives services	Regular classroom	Regular classroom with regular peers "to the maximum extent appropriate"	Wide ranging, from regular education classrooms (inclusion) to pullout for special education classrooms, to offsite day school programs, to 24 hr/day residential schools
Review of the plan	As needed	Plan reviewed at least every year	At least every year plan is reviewed, and every 3 yrs the student is retested to see if still qualifies
Disciplinary actions	Usually not applicable	If "manifestation hearing" indicates student's impairment or disability caused misbehavior, then student cannot be suspended/expelled; school is not required to provide free, appropriate education for suspended or expelled students	If "manifestation hearing" indicates student's disability caused misbehavior, then student cannot be suspended/expelled; if student is suspended or expelled, school must still provide free, appropriate education
Appeal recourses	None provided	School may alter 504 Plan immediately should circumstances indicate need; "notice" may be provided verbally; family may appeal to the Office for Civil Rights if perceive school is discriminating against child because of a disability	School must provide "prior written notice" before changes in educational plan or placement are made; family may appeal decisions or plan to local then State departments of education

FIGURE 7.3.1. **A:** Determining special education eligibility. **B:** School service plans for students with psychiatric disorders.

TABLE 7.3.4

COMPONENTS OF AN INDIVIDUALIZED EDUCATIONAL PROGRAM (IEP)

Usual Components

Component	Example	Comments
Present level of functioning	Although in the 5th grade, [student] is currently reading at 3rd grade level.	Both strengths and weaknesses should be described, with current functioning identified for each area of need requiring a goal
Educational goals	In normal classroom discussions, [student] will repeat back accurately instructions for a task, 4/5 times daily.	Goals should include: (1) circumstances or setting; (2) observable behavior; and (3) performance measure, as well as staff person responsible for implementing
Educational accommodations and modifications	[Student] will be allowed to take tests verbally or untimed.	Intervention necessary to allow student to access curriculum, or how curriculum will be modified
Special education and related services	[Student] will receive specialized reading instruction 60 min/day for 4 days/wk in the learning center.	Clarification of staff with special expertise to assist student and how that will occur (teaching, consult to teacher, group instruction, etc.)
Placement and participation specifications	[Student] will receive reading, math, and social group instruction in a pullout resource classroom.	Least restrictive environment for student to receive services
Transition services planning	[Student] will work at _______ 2 days/wk starting April 1st.	For all students by age 16, although may start at age 14
Transfer of rights planning	[Student] is aware of right to participate.	Student informed, allowed to participate by age 16, and parental rights transfer when reaches age 18.
Additional Components/Related Services		
Adapted physical education	[Student] will be allowed to ride bicycle for PE requirement in place of group PE.	Changes in physical education requirements based on disability
Behavioral intervention plan	[Student] will access [Staff] and follow de-escalation steps when irritated.	A *Functional Assessment of Behavior* usually includes (1) antecedents to the negative behaviors, (2) specific negative behavior, and (3) consequences (benefits) of this behavior so that interventions can occur at any of these three points
Counseling services	[Student] will receive 30 min of individual counseling per wk.	Counseling is usually to help student function better at school; counseling may include parents or family training
Extended school year services	[Student] will receive tutoring 2 hr/day for 4 wks in Summer.	Extended-year services are required to “prevent regression” rather than to increase new skills throughout the year
Occupational therapy	[Student] will receive keyboarding training.	Often includes additional training in activities of daily living; may also include special cushions, devices, or techniques to address sensory-motor symptoms

Physical therapy	[Student] will practice writing with special paper and pencil.	Includes development of gross and fine motor skills
School health services	[Student] will have blood pressure checked weekly.	Medication administration, vital sign or other check (blood glucose, etc.), or nutritional services may occur
Speech–language therapy	[Student] will receive speech therapy with another student 30 min/wk to develop conversation skills.	Includes social-pragmatic training as well as training for dysarticulation
Transportation services	[Student] will ride a van with an assistant.	May include special vehicles or configurations based on student's needs

The authority of school officials has increased with subsequent amendments to the IDEA. At this time, administrators may immediately remove and place a student into an alternative setting if the student brings a weapon to school or to a school function, or if the student sells, uses, or attempts to buy drugs at school or at a school function. The alternative placement is decided by an emergency IEP team meeting. The amendments also include a provision for dealing with other conduct considered to be dangerous. School officials can suspend a child for up to 10 days (total within a school year) and in the interim ask for an expedited administrative hearing at which an order changing placement can be obtained on a showing by "substantial evidence that maintaining the current placement of the child is substantially likely to result in injury to the child or to others." This process can be repeated during a formal dispute by parents over the change of placement or of the appropriateness of the alternative placement.

Important protections for students have also emerged with amendments to the IDEA. For students with disruptive behaviors, the school may be required to conduct a *manifestation determination review* to determine if a student's misbehaviors are a result of a disability. For example, a child with Tourette's might not be able to sit still, or quietly, because of tics, or a student with bipolar disorder might not be deemed capable of speaking softly or remaining seated. The educational team must determine whether the student understood that his or her behavior was inappropriate, whether the student could control the behavior, and whether the IEP and placement had been appropriate. If it is determined that the misconduct was not a manifestation of the child's disability, the school may apply the same disciplinary sanctions to that child as apply to children without disabilities. If the conduct is found to be a manifestation of the disability, the school is obligated to continue programming, embodied in an IEP, in the alternative setting. Children subject to discipline, but who have not been evaluated for and/or identified as eligible for special education, but who are suspected of having qualifying disabilities are entitled to the same protections as children already found eligible.

The IDEA provides extensive procedural protections to parents of children with

disabilities, including “the right to participate in the development of the IEP, the right to independent evaluations, the right to inspect educational records” and “the opportunity to present complaints with respect to any matter relating to the identification, evaluation, or educational placement of the child, or the provision of a free appropriate public education to such child.” Such a proceeding, referred to as a *due process* hearing, requires a neutral adjudicator, a right to counsel at the parent’s expense, and the right to present evidence and cross-examine witnesses. If dissatisfied, either party has a right to judicial review in the appropriate state or federal court.

EDUCATIONAL INTERVENTIONS FOR STUDENTS WITH SELECTED PSYCHIATRIC DISORDERS

Psychiatrists may be asked for specific classroom and school environment modifications by the school, the legal system, and/or the parents. The sample interventions in Table 7.3.5, derived from www.schoolpsychiatry.org, may be appropriate for particular students having various psychiatric disorders, depending on the needs of the child and the resources of the school. Such interventions should always be paired with the individual needs of each student rather than categorically applied to every student with that disorder, so interventions addressing several comorbid conditions are often required. Interventions may be adapted to a student’s district service plan, 504 Plan, or to an Individualized Educational Program (IEP) as modifications/accommodations, or informally implemented in regular classroom settings. The success or failure of these interventions often helps clarify whether a child can remain in the current school environment or requires a different educational setting. While students are entitled to an education in the least restrictive environment, this parameter may necessitate a student to receive instruction in a regular classroom, receive some instruction outside the regular classroom, receive all instruction in a self-contained special education classroom, go to a program at another site, or attend an off-site 24-hour/day residential school. Accordingly, the psychiatrist’s report should clarify diagnoses (“rule-out” diagnoses are not helpful to schools), appropriate accommodations for symptoms that impair school progress, recommendations for services (e.g., social pragmatics training through speech therapy), and program recommendations (e.g., staff trained to work with students with autism spectrum disorders). From these recommendations the student’s educational team can identify a specific placement to address the student’s unique needs. Evidence-based interventions have been catalogued increasingly, including the elements common to programs and interventions that appear most effective. The following websites emphasize those interventions with the strongest evidence to date:

www.practicewise.com
http://www.ncbi.nlm.nih.gov/pmc/
www.evidencebasedprograms.org
http://autismpdc.fpg.unc.edu/sites/autismpdc.fpg.unc.edu/files/imce/documents/2EBP-Report.pdf

Examples of evidence-based interventions for psychiatric symptoms and how these can be applied by school staff are provided in Table 7.3.5.

MENTAL HEALTH SERVICES IN SCHOOLS

Approximately 20% of students aged 6 to 17 years currently suffer from significantly impairing psychopathology (see Chapter 3.2.1). Less than one-fifth of these students receive any treatment for these disorders. Minority groups and the uninsured are less likely to receive mental health services. One-quarter of public schools have no counselors, and over half do not have a social worker, yet schools are being asked to deal with more of the mental health needs of their students (16). In addition, reports of increased bullying and school shootings accent the importance of recognizing and responding to the psychic pain of students.

School psychiatry has expanded to address school violence, bullying, substance abuse, trauma and mental health promotion. The after-school setting as a venue for mental health supports has received increased attention, with increased rates of crime, drug use, and sexual behaviors during the afternoon hours when many youth are without adult supervision. Psychiatrists and other mental health professionals continue to refine child psychiatry’s role in schools, incorporating business and educational principles in effecting change and improving system functioning. Modern school consultation focuses more on early identification and intervention at the individual and system levels to help attain short-term educational and behavioral goals and to prevent later long-term negative outcomes.

School-Based Mental Health Services

Although many psychiatrists partner as independent consultants to schools, some work as part of community-partnered school mental health programs. Approximately two-thirds of schools report partnering with community providers, often outpatient community mental health centers, to provide school-based services. Community mental health program partners may include community mental health centers, hospitals, and universities. Such partners are increasingly contracting with schools to provide a full array of tiered services to students in both general and special education, including universal mental health promotion activities, selective prevention, and indicated early intervention services such as clinical assessment and

treatment (17).

Prominent in several states (e.g., Hawaii, Maryland, Minnesota, and Ohio), as well as cities (e.g., Baltimore, Dallas, Los Angeles, Nashville), community-partnered (also termed "expanded" or "comprehensive") school mental health programs have continued to proliferate and address the needs of students, particularly when they might otherwise not have access to mental health services. On-site school mental health services provide greater access to youth and their families, with less stigma and the opportunity for early intervention (18,19). The shared goals of these partnerships emphasize improving student behavior, addressing barriers to learning, increasing access to mental health care, and improving student attendance and academic achievement. This type of programming relies on collaborative partnerships between school systems and community programs so that school-employed mental health professionals are meaningfully supported by community mental health providers (20).

TABLE 7.3.5

SCHOOL INTERVENTIONS FOR SPECIFIC PSYCHIATRIC SYMPTOMS

SCHOOL-BASED INTERVENTIONS		
	Interventions	Examples
Target Symptoms	To Be Implemented by Teacher/School Staff	To Be Adapted According to Student's Age, Interests, Capabilities
Anxiety		
Worry	Forewarn the student of transitions, and have "tasks" for the student to focus on during transitions	If the student is worried about a school trip, provide tasks that distract from anxiety, such as checking attendance, or holding the door at the site.
	Devise a desensitization approach agreeable to the student	If the student fears speaking in front of the class, allow the student to: have the speech read by a peer; read the speech into a recorder outside class; do the speech with a peer reading some part.
	Help the student examine other perspectives	The student says "I can't go to the school dance because everyone will notice that I'm nervous." Ask the student: "how would your best friend/someone you admire handle a situation like this? What does your friend think you should do?"
	Provide the student with competing responses to negative thoughts or behaviors	The student says "I'm afraid I'll start crying in class." Ask the student: "if you start to feel sad, what can you do before you start to cry? Can you distract yourself by doodling?"
Emotionality	Provide specific steps the student can take to relax, or provide a relaxation ritual	Take three deep breaths; tense fingers or toes for 5 s, then relax.

	Provide alternative foci to distract the student from somatic symptoms	Provide the student a phrase to think of or an activity (doing three problems then standing up, 10 problems then walking to the fountain).
Separation difficulty	Provide desirable activity/responsibility for the student upon entering school	Before school begins, allow the student to feed fish, clean boards, play with peers, or discuss music/sports with another student who shares interests.
	Provide times during the school day for the student to convey brief (30 second) messages to his/her family	Have a brief script/message the student can phone to a parent ("Hi Mom, made it through Science—now we're going to make penguins in art class. I love you.); prepare the parent not to overreact to tearful messages.
	Have a parent send notes to the student to read as a reward for staying at school for increasing intervals	Have a parent place a brief note to the student in his/her lunchbox that the student can read at lunchtime ("Dear [name], I know you're at lunch now—enjoy the cupcake. Have a great afternoon, and when I pick you up today we'll get to play soccer. Love, Dad")
Social fears	Allow the student to observe several other students before attempting a task	If the student resists speaking in class, allow the student to observe others, focusing on how they start, how long they speak, where they look, and how they stop
	Have the student rehearse social skills in a smaller or more relaxed setting	In a small group facilitated by a counselor, have students review and role play how to make and keep friends. Give students homework to practice skills in other settings (classroom, playground, home play date, etc.)
Obsessive thoughts	Establish acceptable teacher comments to "unstick" the student when he/she is obsessing	With the student and parents, identify useful statements to break an obsessive cycle ("Move to your seat on 3—1, 2, 3." "Now think about your coach—what would he/she say to your "rut," "stuck moments?")
	Allow the student to dictate or tape record if he/she cannot touch the pencil or paper	Teacher or voice dictation software can "transcribe" the student's ideas to avoid touching/erasing the paper
Compulsions	Allow the student to alter the work sequence	If the student gets stuck doing problems in a certain way, allow the student to start with even numbers, or start from the end and work backwards to #1
	Have the student identify and substitute less disruptive compulsive behaviors	Allow the student to touch underneath the desk, flex fingers, or do versions of compulsions that are not disruptive to others
Mood Symptoms		
Sad mood	Check in with the student to quantify his/her mood status each day	Allow the student to complete a mood scale (10 = very happy to 1 = very sad) at first check-in time each morning
	Help the student	Examine specific events that led to the student's

	identify "all the evidence" surrounding his/her negative perceptions of self or events	conclusion that "I'm no good." "What happened that led to this conclusion? Did anything happen that disputes your conclusion? What else happened in your other classes that day?
	Help the student identify automatic negative thoughts	The student says "I'm no fun. No one wants to be around/play with me." Ask the student: "What happened that made you think this?" or "what evidence leads you to reach this conclusion?"
	Acknowledge the student's feelings (rather than dispute/argue with feelings)	"It's sad when…," "discouraging," "frustrating" rather than "it's not so bad," or "aw, come on, things will be better soon"
Irritable mood	Model appropriate responses to replace irritable responses	Provide an alternative, appropriate comment: "I know you have something important to say, and I want to hear it, but I can't hear your point when you use sarcasm. It sounds like your point (without sarcasm) is _______." Could you please say your point again without relying on sarcasm?"
	Allow the student to take him/herself out of a situation (self-timeout) when irritability is starting to disrupt others	Provide specific steps for the student to remove him/herself from situations ("I [student)] feel myself getting frustrated, so I am going to leave this kickball game and swing on the swings for 5 min. After I watch others, and think I understand what I'm supposed to do, I'll try kickball again.")
	Provide opportunities for the student to "fix" problems or inappropriate classroom behaviors	Allow the student a chance to "redo" with an appropriate comment or behavior; if the student tears up paper, allow him/her to tape it together.
Manic mood	Allow the student to complete schoolwork or tests in a less stimulating environment	Identify a calm, comfortable area (with limited distractions, noise, and sensory stimuli) where the student can complete work/tests
	Allow the student alternative modes of expression if he/she cannot verbalize in a useful way or is speaking too rapidly	Provide the student with an opportunity to write, dictate, or draw ideas
	Allow the student to have homebound instruction during manic periods	Determine the conditions that warrant homebound instruction (for example, the student is sleeping during the school day while awake at night; the student's fears or delusions are causing conflicts in the classroom). Home instruction may need to be provided by specialized (therapeutically trained) staff.
Appetite changes	Encourage the student to use snacks and/or physical activity to enhance	Provide snack breaks when the student finishes tasks. Encourage the student to be physically active at appropriate times by taking attendance to the office, standing and moving books, etc.

	functioning	
	Change food reinforcers to nonedibles	Instead of chips or candy, reinforce the student with stickers, computer time, or points to earn a lunch date with a preferred peer (if increased appetite/weight)
Fatigue; energy loss	Augment classroom instruction with recordings of instruction	Tape-record or videotape lectures and provide recordings to the student
	Identify study partners who can support and assist with assignments	Allow a peer to study with the student and to assist in academic assignments
	Introduce physical activity throughout the day	Provide the student physical responsibilities (taking attendance to the office, emptying trash, putting up class materials) throughout the day to encourage physical activity
	Grade the student based on work completed or attempted (rather than work assigned)	Grade items completed (e.g., even numbers only), and do not count the items the student does not get to (odd items)
Suicidal or self-harm thoughts	Identify appropriate methods for expressing feelings of hopelessness or self-destruction	Encourage the student to draw pictures, write songs or poems, or use sculpting to depict feelings of sadness, anger or despair
	Establish a hierarchy of people for the student and staff to contact if the student has suicidal thoughts	Specify multiple staff and treatment providers, and the order or circumstances for contacting them, when the student is feeling or appearing unsafe
Psychosis Symptoms		
Hallucinations delusions	Identify and avoid the student's exposure to known distressing stimuli	Clarify with the student or family the items, places, or topics that trigger delusional thinking and find alternatives, particularly when the student is stressed or currently experiencing psychosis symptoms
	Allow the student alternative schoolwork or activities to avoid provoking delusions	If the student cannot proceed with a task, provide an alternative, "grounding" task which requires little creativity, such as reading, moving items, or doing rote tasks
	Devise steps to employ when the student is delusional or hallucinating	Employ a series of steps to de-escalate the student when he/she is becoming more delusional (first: change topic, second: change activity, third: change setting, fourth: change staff).
Attention-Deficit Hyperactivity Symptoms		
Inattention	Define classroom expectations in positive terms	"Please sit down, get our your pencils and paper, and let's look at the board to find our first task"
	Problem solving approach	S-A-C-T-A (Situation-Alternatives-Consequences of alternatives-Try best one-Attempt another if first

		unsuccessful
	Affix materials to the student’s desk	Keep regularly needed materials such as pencils attached to the student’s desk where they cannot be misplaced
	Provide organizational devices in the classroom	Use colored folders to distinguish math vs. reading vs. social studies work; use a clipboard to hold papers or current activities
	Keep a sample model of a correctly formatted paper for the student to refer to	Keep formatted (even laminated) paper showing where name, date, etc., should appear on the student’s assignments
	Have the student repeat directions back to the teacher	After giving directions, have the student repeat back the sequence
	Provide check-in points during lessons	“Raise your hand when you finish the first three problems, and we’ll come by to check them.”
	Provide untimed or extended time for tests or assignments	Allow the student to work at his/her own pace, even “rest,” so he/she can demonstrate all that he/she has learned
	Diminish external distractions	Minimize noise in the classroom by using headphones, tennis balls on chair legs, or rugs
	Use a daily progress book or email between school and parents	Send a small book or email between school and home to keep parents and teacher aware of the student’s daily progress, and of any events that might influence the student’s attention
Hyperactivity	Clarify volume and movement expectations of the student before unstructured activities	“As we go through the hall, we’ll only use our whispering voices if we have to speak, then in the lunchroom we’ll remember to use our ‘inside’ voices”
	Specify acceptable personal space	Clarify space boundaries with visuals such as “each person has the space of four tiles.” Put tape on the floor to demonstrate that others stand outside this distance
Impulsivity	Establish a waiting routine	Develop with the student a multistep plan for waiting, such as “count to five then raise your hand and look the teacher in the eyes”
	When behavior is inappropriate, describe what you want (vs. what you do not want) and reinforce	During misbehavior, clarify what you want the student to do rather than describing the misbehavior (“next time you turn in a paper, make sure your name is at the top” instead of “don’t turn in a paper without your name at the top”)
Autism Spectrum Symptoms		
Communication difficulties	Create situations to motivate language use	Structure situations so that language becomes helpful (choose the flavor of ice cream from a list)
	Allow the student time to process information and	Provide sufficient time for the student to understand direction and to respond (wait 10 s for student response)

	respond	
	Ensure that the teacher is positioned strategically to engage the student's attention	Align at the student's eye level. Touch the student's desk or chair while quietly saying something like, "Look at the —— (checklist or material) and listen. I need you to know…….." Pause to give the student time to shift attention.
	Provide choice boards for the student to communicate preferred activities	Show the student different options for tasks (picture of a book [for reading], food [for snack], counting cubes [for math])
	Develop visual cues to reduce sensory overload	Devise visual cues such as hand signals or use of pictures to diminish reliance on verbal and physical prompts
	Use scaffolding techniques to promote spontaneous language	Add "parts" (sentence starters, transition statements to connect ideas) to facilitate conversation with the student
Difficulties with social interaction	Pair the student with a "typical" peer/buddy to help carry out social interactions in structured settings	Team the student with a "typical" peer during a structured recess kickball game to show the student how to kick, run, and catch.
	Divide social skills into successive steps and teach the steps incrementally	Break down social encounters and teach multiple ways to accomplish each part (you can introduce yourself by saying your name, by asking what the other person is doing, by showing the other person an interesting object, by just saying "hi," or by having a friend who already knows someone introduce that person)
	Provide explicit teaching about how to start conversations, respond to comments, and end conversations	Describe specific phrases and behaviors to create conversations ("stand this far from a person, look at their eyes, say 'hi', ask if they want to play four square with you," "say 'maybe another time' if they say 'no.')
Restrictive routines/interests	Provide alternative tasks, particularly when the student is sensory overloaded	Allow the student several choices within his/her daily tasks. The student can choose the order of tasks, or when/where to take a break.
	Specify the student's routine for asking questions or describing topics when the student seeks or presents information	Explain that the procedure for asking questions is to limit him/herself to two questions, then allow others to ask ("You can ask the two most important questions to begin work.")
Sensory issues Include extreme over-sensitivity or under-responsiveness to sound, light, or other sources of	To control sensory inputs, allow the student to be first or last in line or to leave class early	Allow the student to change classes 5 min before the other students, or have him/her hold the door open for other students and then join the end of the line as the "caboose"
	Teach students who	Practice humming loudly and softly and have the student role-play appropriate times to hum loudly

stimulation	use distracting vocalizations or other self-stimulating behaviors to employ other intrusive vocalizations or behaviors	and appropriate times to hum softly

Intervention and Prevention Programs

There are many evidence-based mental health promotion, prevention and early intervention programs that target the full continuum of supports for all students in school, including those at risk and with identified problems. Successful school models integrate the school, family, and community in coordinating services. Common elements in successful intervention and prevention programs include: youth being connected to a trusted adult, access and coordination of appropriate programs and services with ongoing evaluation, program continuity with school support, and emphasis on early identification and intervention. Psychiatrists can help schools identify and implement appropriate programs depending on the needs and resources of the school system. Several repositories have been developed to guide schools and consulting professionals in the selection of programming to meet their student population and target outcomes.

Websites for Evidence-Based Student Interventions

DELINQUENCY/VIOLENCE/AT-RISK BEHAVIORS:

1. **FindYouthInfo.gov:** This program/site features evidence-based programs that prevent and reduce delinquency or other youth problem behaviors (e.g., drug and alcohol use). Programs focus on one of the following problem behaviors: delinquency; violence; youth gang involvement; alcohol, tobacco, and drug use; family functioning; trauma exposure; or sexual activity/exploitation.
2. Promising Practices Network (PPN) on Children, Families and Communities (**http://www.promisingpractices.net/programs.asp**): The PPN site features summaries of programs and practices that improve outcomes for children.
3. Blueprints for Violence Prevention Model Programs Selection Criteria (**http://www.colorado.edu/cspv/blueprints/model/criteria.html**): Blueprints programs have the highest standards by showing evidence of a *deterrent* effect with a strong research design, *sustained* effect, and multiple site *replication.*

SOCIAL–EMOTIONAL LEARNING (SEL):

4. The Collaborative for Academic, Social, and Emotional Learning (CASEL) (**http://www.casel.org/programs/selecting.php**): ”CASEL Select” programs

provide outstanding coverage in five essential SEL skill areas; have at least one well-designed evaluation study demonstrating their effectiveness; and offer professional development supports beyond the initial training.

MULTITIERED SYSTEMS OF BEHAVIORAL SUPPORT:

5. Positive Behavioral Intervention System (PBIS): **https://www.pbis.org/school/school-mental-health/interconnected-systems**: PBIS provides a school-wide program to enhance positive behavior in the school system.

TIER 2					
Targeted small-group prevention and promotion for at-risk students.	• Bounce Back • Cognitive-Behavioral Interventions for Trauma in Schools (CBITS) • Support for Students Exposed to Trauma (SSET)	• CARE (Care, Assess, Respond, Empower) • The C.A.T. Project • Coping Cat	• CARE (Care, Assess, Respond, Empower)	• Aggression Replacement Training (ART) • CARE (Care, Assess, Respond, Empower) • Coping Power • I Can Problem Solve: Raising a Thinking Child (ICPS) • Incredible Years • Nurturing Parenting Program • Strengthening Families Program (SFP)	
TIER 3					
More intensive, individualized interventions for students experiencing a mental health challenge.	• Trauma-Focused Cognitive-Behavioral Therapy (TF-CBT)	• The C.A.T. Project • Coping Cat	• Interpersonal Psychotherapy for Depressed Adolescents (IPT-A)	• Multisystemic Therapy (MST) • Nurturing Parenting Program	

Tier III: Few Students
Apparent behavioral health needs

- Multi-Systemic Therapy (MST)
- Nurturing Parent Program

Tier II: Some Students
At risk for behavioral health concerns

- Aggression Replacement Therapy (ART)
- CARE (Care, Assesses, Respond, Empower)
- Coping Power
- I Can Problem Solve: Raising a Thinking Child (ICPS)
- Incredible Years
- Nurturing Parent Program
- Strengthening Families Program (SFP)

Tier I: All Students
Regardless of behavioral health risk

- 4 R's
- Al's Pals
- Caring School Community
- Good Behavior Game (GBG)
- HighScope Educational Approach for Preschool
- Life Skills Training (LST)
- Lion's Quest Skills for Adolescence
- Michigan Model for Health
- MindUP
- Nurturing Parent Program

- Olweus Bully Prevention Program
- Open Circle
- Peaceworks: Peacemaking Skills for Little Kids
- Promoting Alternative Thinking Strategies (PATHS)
- PATHS to PAX
- Project ACHIEVE
- Raising Healthy Children
- Resolving Conflict Creatively Program
- RULER Approach
- Second Step Violence Prevention Program
- Social Decision Making/Problem Solving Program
- Steps to Respect
- The Stop and Think Social Skills Program for Schools
- Teaching Students to be Peacemakers (Peacemakers)
- Tools of the Mind

FIGURE 7.3.2. Example of school services to address problems by tier: conduct/aggression.

Selection and implementation of school mental health interventions has more recently aligned with the education system's multitiered approach to academic support for all students, termed *Response to Intervention (RtI).* Essentially, schools use a system of screening and early identification and intervention to identify struggling students and to respond as early as possible with individualized academic supports. Many schools are applying this framework to student mental health, organizing their decision making within a multitiered system of support (MTSS), in which students are identified to receive universal (Tier 1), selected (Tier 2) and/or indicated (Tier 3) supports.

Universal mental health promotion services and supports (Tier 1) are mental health–related activities, including promotion of positive social, emotional, and behavioral skills and wellness which are designed to meet the needs of all students regardless of whether or not they are at risk for mental health problems. About 80% to 85% of students in a school can be successfully addressed through Tier 1 approaches. These activities can be implemented school-wide, at the grade level, and/or at the classroom level. When there is a strong foundation in promoting wellness and positive life skills, concerns or problems can be prevented or significantly reduced. *Selective* services and supports (Tier 2) to address mental health concerns are provided for groups of students, usually between 10% and 15% of students in a school with more complex needs than those who fit in Tier 1, who have been identified through needs assessments and school teaming processes as

being at risk for a given concern or problem. When problems are identified early and supports put in place, positive youth development is promoted and problems can be eliminated or reduced. Sometimes these are referred to as mental health "prevention" or "secondary" prevention services. Finally, *indicated* services and supports (Tier 3) are individualized to meet the unique needs of each student who is already displaying a particular concern or problem and displaying significant functional impairment. Tier 3 is usually necessary for approximately 5% of students in a typical school. Sometimes these are referred to as mental health "intervention" or "tertiary" or intensive services. Child psychiatrists are more likely to see patients who may fit in Tiers 2 and 3, where more specialized mental health services are needed.

An example of evidence-based interventions, categorized by tier and target outcome/problem is presented in Table 7.3.6. An example of "tiering" of these evidence-based interventions, is shown in Figure 7.3.2, which is derived from the websites for evidence-based programs described above.

Video Consultation

Video technology has improved alternatives available to schools seeking psychiatric input, particularly those in remote areas with limited access to mental health services. Some of these programs provide indirect service to schools through consultation with school staff provided by a psychiatrist or psychologist around mental health issues impacting students (21). Video consultation can provide individual student evaluations, indirect consultation to teachers and school staff, and opportunities to demonstrate interventions for students whose psychiatric issues impair learning (22). Such technologic advances increase options for collaboration with schools, although new considerations such as billing, confidentiality parameters, providing consultation or treatment across states, receptiveness by staff and students, and potential losses of important observations by not being "in the room" must be anticipated when employing this modality (23). Child psychiatrists have found telepsychiatry in schools to be acceptable, feasible, and an effective vehicle for reducing burden of seeing children across multiple sites (24).

7.4 The Law

CHAPTER 7.4.1 ■ THE CHILD AND ADOLESCENT PSYCHIATRIST IN COURT

CHRISTOPHER R. THOMAS

This chapter is a guide for child and adolescent psychiatrists on how to work with the legal system; clarifying the complex legal realm and hopefully preparing child and adolescent psychiatrists to be more effective when interacting with the courts. Whether or not a child and adolescent psychiatrist has any interest in forensic work, there may come a time when he or she will have to deal with the legal system. There are many situations in which child and adolescent psychiatrists may become involved with the legal system as part of their practice, including not only forensic testimony, but also legal cases involving their patients. The chapter begins with a brief overview followed by sections that explain the two distinct roles that a child and adolescent psychiatrist may serve within the court. Many of the dilemmas encountered will not have a clear-cut answer and since factors within any legal situation are complex and often jurisdiction-specific, it is more important for the child and adolescent psychiatrist to not only understand the general guiding principles but also the laws and court procedures where they practice in order to be able to apply these guidelines appropriately (Table 7.4.1.1).

TABLE 7.4.1.1

DEFINITIONS OF LEGAL TERMS

Confidentiality: Secrecy; the state of having the dissemination of certain information restricted.

Cross-examination: The questioning of a witness at a trial of hearing by the party opposed to the party who called the witness to testify. The purpose of cross-examination is to discredit a witness before the fact finder in any of several ways, as by bringing out contradictions and improbabilities in earlier testimony, by suggesting doubts to the witness, and by trapping the witness into admissions that weaken the testimony. The cross-examiner is allowed to ask leading questions but is traditionally limited to matters covered on direct examination and to credibility issues.

Defendant: A person sued in a civil proceeding or accused in a criminal proceeding.

Deposition: A witness's out-of-court testimony that is reduced to writing (usually by a court reporter) for later use in court for discovery purposes.

Direct examination: The first questioning of a witness in a trial or other proceedings, conducted by the party who called the witness to testify.

Expert witness: A witness qualified by knowledge, skill, experience, training, or education to provide a scientific, technical, or other specialized opinion about the evidence or a fact issue.

Fact witness: A witness who may testify only to information that is based on firsthand knowledge.

Guardian ad litem: A caretaker, usually a lawyer, appointed by the court to appear in a lawsuit on behalf of an incompetent or minor party.

Plaintiff: The party who brings a civil suit in a court of law.

Preponderance of evidence: The greater weight of the evidence; superior evidentiary weight that, though not sufficient to free the mind wholly from all reasonable doubt, is still sufficient to incline a fair and impartial mind to one side of the issue rather than the other. It is also referred to as preponderance of proof or balance of probability.

Privilege: A special legal right, exemption, or immunity granted to a person or class of persons; an exception to a duty.

Reasonable doubt: The doubt that prevents one from being firmly convinced of a defendant's guilt, or the belief that there is a real possibility that a defendant is not guilty.
Redirect examination: A second examination, after cross-examination, the scope ordinarily being limited to matters covered during cross-examination.
Subpoena: A writ commanding a person to appear before a court or other tribunal, subject to a penalty for failing to comply.
Subpoena duces tecum: A subpoena ordering the witness to appear and to bring specified documents or records.
Voir dire: A preliminary examination to determine the qualifications of a prospective witness or evidence.

OVERVIEW

The court structure in the United States of America has both state and federal systems. The state and federal courts consist of general trial courts that can have appellate review. That means that at times a case can be decided by a lower court, but a party in the case can later appeal the decision or proceedings to a higher court. General courts in both systems handle criminal and civil cases. Civil cases encompass a wide variety of legal actions ranging from personal injury claims to custody decisions, while criminal courts involve cases brought by the government against a defendant for allegedly committing illegal acts. Psychiatrists are increasingly being called upon to testify in cases involving children and adolescents for varying purposes in both types of legal proceedings.

The state legal systems also provide a series of specialized courts for matters that are better handled in a court of limited jurisdiction. Juvenile court is the type of specialized civil court that is most familiar to many child and adolescent psychiatrists. The creation of the juvenile court in the United States in 1899 focused efforts on the rehabilitation of delinquents rather than their punishment and thus was meant to be different from adult criminal courts. Problems in protecting the rights of youth in the juvenile justice system as well as concerns that it was not effective in preventing recidivism have resulted in court rulings and legal statutes that have made the juvenile justice operate more like the adult criminal court. Over the past few decades what were previously only adult forensic psychiatric evaluations, such as competency examinations, are now being performed in juvenile court.

The extent to which a child and adolescent psychiatrist needs to be familiar with the court system will depend upon their practice. Those who are involved in expert forensic work need to and will be held accountable to have an understanding of the various court systems and different procedures to a much greater extent than the child and adolescent psychiatrist whose only involvement with the court is when subpoenaed as a fact witness.

Many psychiatrists are understandably apprehensive of any contact with the court. Unfamiliarity with the processes and procedures of the judicial system is a major factor in these misgivings and anxieties. Most information child and adolescent

psychiatrists have about the judicial system is based on fictional depictions from books, television, and movies, or from news reports about high-profile cases. Imagine the distorted view others have of child and adolescent psychiatry based on the same sources and it is easy to see how unfamiliarity exists on both sides of psychiatry and the law. It is not only the difficulty of dealing with unfamiliar rules, but also very different approaches to evaluating information and making decisions from those used in medicine. While child and adolescent psychiatrists frequently must address conflict in the clinical care of patients, the methods of reaching resolution focus on reducing confrontation through amicable mediation or reconciliation. In contrast, the judicial system relies primarily on an adversarial approach to reach a decision, where opposing parties are allowed the opportunity to present their strongest arguments supporting their position and attacking the other side so that a judge or jury may decide between the two. The aggression of cross-examination can be very intimidating and feel more like a personal attack rather than a dispute of the relevant facts and expert opinions. Medical professionals are often baffled by judicial rulings that go against their opinions or recommendations when they fail to see that the court must consider and balance a wider range of viewpoints or evidence. In addition, the court must follow established procedures and precedent in handling any testimony and evidence it considers. The need to preserve the process over any individual case can appear confusing when certain evidence is removed from consideration. Previous experience with litigious families and rising general concern about medical malpractice also add to misgivings about any contact with the courts for child and adolescent psychiatrists. As in any consultation setting, knowledge and practice can correct most uncertainties and improve the ability of the child and adolescent psychiatrist working with judges and attorneys.

FACT WITNESS

Child and adolescent psychiatrists may be called to testify as a fact witness in a hearing or trial. Fact witnesses provide the most common type of testimony in court, reporting things that they directly saw, heard, or did; in other words, facts.

Process of Involvement

Subpoena

At times, child and adolescent psychiatrists become involved with the legal system by being served a subpoena. A subpoena is a legal summons that requires someone to either appear at a specified proceeding, produce specified documents, or both. In most cases, being served with a subpoena does not mean that the child and adolescent psychiatrist has done something wrong. Generally, it simply means that the recipient

possesses information that is relevant to a legal dispute involving other parties. If the child and adolescent psychiatrist works for an organization, be it state or private, they should contact their legal department and inform them of the subpoena as soon as possible. If a recipient is in private practice, he or she may want to discuss the subpoena with an attorney as it may have later implications related to another type of legal claim. The attorney named on the subpoena does not need to be contacted, but may be called to clarify the reason for the issuance of the request. While the child and adolescent psychiatrist may ask the attorney questions about the pending legal case, it is important to remember that attorneys, including those who work for the state or other government agencies, can lack an understanding of privacy laws that direct clinical practice disclosure of information regarding protected health information. It is possible for the child and adolescent psychiatrist to violate the Health Insurance Portability and Accountability Act (HIPAA) Privacy Rule under these circumstances, as subpoenas do not necessarily provide the authority to release confidential personal health information.

Prior to providing any information requested in the subpoena, the child and adolescent psychiatrist needs to ensure that the patient or the guardian, as in the case of a minor child, who controls the privilege to information has consented to the information's release, there has been a judicial determination that the privilege does not apply or privilege has been waived by some action of the patient's, such as making mental health a part of the legal claim. If there has been no waiver by the patient or when it is uncertain who has the ability to consent, such as in custody disputes involving divorced parents, the child and adolescent psychiatrist should contact the issuing attorney to notify him or her that they will not be able to provide any information about the patient without authorization by the patient, the valid representative, or a court order. If the child and adolescent psychiatrist is not provided with any of the above, then he or she must still appear at the court proceeding or deposition and provide information about himself or herself, but when asked information regarding the patient the psychiatrist would respond that the information is confidential and privileged and follow the direction of the judge if in court (1).

There are occasions when the underlying legal dispute may involve, or have the potential to involve, professional liability claims that could expose the practitioner to legal action and would involve different HIPAA regulations that are not covered in this chapter and for which the reader is referred to the chapter on medical malpractice.

As mentioned above, the subpoena could also require the production of all the relevant medical records. Child and adolescent psychiatrists that work for an institution or do contract work are not the legal custodian of the medical records. Any subpoenas requesting copies of medical records should be referred to the department controlling those documents. For clinicians in private practice however,

arrangements for the entire medical record that is responsive to the subpoena must be made available.

The child and adolescent psychiatrist may be asked by the family of their patients or the patients themselves to provide legal testimony regarding psychiatric treatment rendered. This may at times be appropriate to agree to as it may offer more flexibility regarding appearance versus a subpoena. However, when the testimony requested is regarding an expert opinion and not a rendition of treatment facts, the requesting party should be informed of the impropriety of the request and that this type of service is best handled by a nontreating psychiatrist. Sometimes a parent might ask for a letter from a psychiatrist providing treatment in support of their fitness in parenting, and it is necessary to explain that such an evaluation has not been part of the treatment, would potentially undermine further care, and is best provided by another psychiatrist. Further information regarding the role of forensic testimony by child and adolescent psychiatrists is detailed in the following section. The child and adolescent psychiatrist should avoid serving as both treating clinician and forensic expert for any given individual.

General Court Procedures

For the child and adolescent psychiatrist who has never been to court before, it is strongly recommended to visit the courthouse prior to testifying. Knowing where to park, where the courtroom in located, where to sit, and the general layout of the courtroom can be helpful to alleviate anxiety and increase the overall comfort level. Juvenile, or family, courts are generally not open to the public and only the parties involved in the current case are allowed attendance without prior permission.

The child and adolescent psychiatrist should dress appropriately for court with either a suit or blazer for both men and women. If bringing files into court they should be contained properly and organized for ease, but avoid unnecessary items to avoid delay with security clearance. Cell phones and pagers are not allowed to be on during court, so other arrangements for coverage will be required. When the physician arrives at court it is important to let the attorneys be aware of the arrival and any time constraints. Although the psychiatrist will be given a specific time for testimony, there is often a significant wait time which is why it is wise to keep the day clear of clinical duties. Many people will bring reading materials to court, but watching the legal process is an interesting way to spend the time as well.

In general, the layout of the courtroom will have a judge presiding on an elevated podium, referred to as a bench, with the court personnel below and to the side of the bench. The attorneys, as there may be several, will be seated at tables facing toward the judge. There will also be a court officer present. If it is an open court, there may be many other people not involved in the case in attendance in the gallery. Depending upon the type of case and the state, a jury may be seated for testimony. When the child

and adolescent psychiatrist is called to testify, he or she is sworn in by the officer of the court and then allowed to sit in the witness box which is usually to the side of the judge. The psychiatrist will be asked to state his or her name and business address. It may be helpful to bring a business card to give to the court reporter for difficult spellings, however many courtrooms now do not have court reporters and use audio recording instead. The testimony, either way, will be entered into the official court record. The psychiatrist will be asked to state his or her credentials, training and experience in a process known as *voir dire*.

The psychiatrist may not bill the patient or an insurance company for time spent for testimony or any aspect of the subpoena. In general, there will be no reimbursement for the time spent in court as a fact witness. This may seem unfair for time taken away from practice but still relate to a patient's case. It is best to consider it as part of the unreimbursed activities of clinical care, such as continuing medical education, that are required in order to practice medicine.

Testimony

There may be many lawyers involved in the case and all of them will have an opportunity to question the psychiatrist. There will be initial questioning by the attorney that has asked the fact witness to testify, which is called direct testimony, after which the opposing attorney will ask further questions related to the topic of the earlier testimony or submitted records, referred to as cross-examination. The first attorney then is able to ask the physician further questions if he or she chooses to "redirect" after which the other attorney has the right to again ask questions. The redirect questions can only be about issues raised during the direct and cross-examinations; no new topics can be introduced. The types of questions and the goals of the questioning will vary depending upon the case and the attorney's relationship to it, as each attorney tries to build a logical argument and set of facts for the court to consider in making a decision while attacking the opposing side's argument and evidence. When the witness is finished with his or her testimony, the judge will excuse him or her and the psychiatrist is now free to leave the courtroom. There may be times when the psychiatrist may have to return to court the next day or on a later date. The court will try to work within the physician's schedule, so a prudent physician may wish to bring an appointment book to expedite the process of rescheduling.

When testifying in court, it is important to speak clearly and loudly and allow time to think about a question before supplying an answer. Since the testimony is being recorded or transcribed, all the responses must be verbal. It is important to remain calm and professional regardless of the actions of the attorneys or others involved in the case. The fact witness should give only factual information and not speculate or give any opinion as part of the answer. The simplest and best advice for testifying in

court seems to often be the hardest to follow: Answer only the question asked and do not offer further information. If a question is not clear, it is always permitted to say it was not understood and request that it be repeated or rephrased. There will be times when a question cannot be answered as posed and the psychiatrist should feel free to say so to the attorney or presiding judge. This may be the case when the fact witness is asked to give only a yes or no answer to misleading questions, which at times the psychiatrist would be able to clarify if given the opportunity. The psychiatrist does not have to be able to answer each question asked. He or she should feel comfortable saying that aspect was not evaluated or he or she simply does not know the answer to the question. If a question of a fact is asked, the witness has the option, which should be exercised liberally, of checking it against the medical records before responding. The law requires that the fact witness testify according to the best memory or with the aid of written records. This allows the psychiatrist to indicate either uncertainty regarding the answers or no recollection regarding the specific question. Sometimes, attorneys and judges may ask questions regarding the psychiatrist's opinion as an expert. It is very important to not cross the boundary as a clinician testifying as a fact witness and instead become an expert witness, as this can compromise treatment. If this occurs, the psychiatrist can politely raise the issue and express to the judge the problem of providing expert opinion and serving as therapist. Sometimes, questions for expert opinion can be deflected by the fact witness clinician by stating that the question was never addressed or evaluated as part of the routine care of the patient, such as evaluating parental fitness.

Attorneys can raise several types of objections during the course of testimony. The specific legal meaning of each type of objection is beyond the scope of this chapter. The psychiatrist only needs to know that when an objection is made that he or she should either not answer the question or stop speaking if in the middle of a reply. The judge will then make a ruling on the objection and then the psychiatrist will be informed if he or she should answer the question, or the attorney will move on to another line of inquiry.

The physician may be asked if his answer is of "medical certainty," which can be a confusing and misleading term to physicians unfamiliar with the legal system. Most competent physicians are able to acknowledge that there is always the possibility of an incorrect diagnosis, treatment, report, or laboratory result regardless of how unlikely the chances. This may serve the psychiatrist well in a clinical setting and enable them to constantly question and reexamine the diagnosis or treatment plan. However, in a court of law the answer to questions of "reasonable medical certainty" will usually be "yes" if the physician has reached a conclusion or diagnosis and started an appropriate treatment plan. The common legal interpretation of "reasonable medical certainty" is that the physician has sufficient information to be assured that the answer is "more likely than not accurate" (2).

There are some tactics that lawyers may use in their questioning that can be

unsettling to the physician who is new to the court process.

1. An attorney will "summarize" the testimony that the physician gave earlier, in direct testimony for example, and then ask the physician if that is correct or use it as an introduction to a question. The physician should be aware of this approach and realize that more often than not the testimony has been altered in some way intentionally. When this occurs, the physician can state that the statement is not entirely correct or have the court record read back.
2. The physician should be aware of any question starting with "Would you agree that … ?" This is because there is often a second question after the seemingly innocuous question the physician probably would not agree with and oftentimes the question is intentionally worded to be misleading. This can be done to have the physician answer the question in a way he or she would not have if phrased otherwise. At the same time, the physician does not need to constantly look for traps and try to outmaneuver the lawyer, but instead stick to the basic principles of testifying as a fact witness.
3. Another type of question that may be difficult for physicians to answer in court is: "Is that everything?" It is more likely than not that the physician has forgotten some information and should thus leave the availability of going back to topics at a later time by responding: "That is everything that I recall at this time."

The witness may have to answer questions about previous violations or legal actions in the course of his or her testimony. There may be occasions when a witness may feel harassed by an attorney, but it is not helpful for the child and adolescent psychiatrist to attempt to argue or show his or her anger while on the stand. Ultimately, if the witness either needs to take a break or feels ill they can indicate this to the presiding judge. The judge may either decide to take a short break or adjourn the testimony until another day.

Depositions

Depositions are that part of litigation called discovery and they serve several purposes. They result in both sides showing their hand, they also give attorneys a chance to observe a witness or the types of arguments the other side plans to introduce, which may shape legal strategy in response. Should the case go to trial, a deposition provides a record of answers given by the child and adolescent psychiatrist that, if contradicted in subsequent court testimony, could raise the question of credibility of the practitioner. Deciding to have personal legal counsel present for deposition or testimony depends on the circumstances, but most situations present little or no exposure to the child and adolescent psychiatrist. However, there may be valid reasons why an attorney would prepare and/or accompany a child and adolescent psychiatrist. If the case is volatile or may have further legal implications, it would be prudent to discuss with personal counsel.

If required to by the subpoena and with valid authorization, the psychiatrist may be required to bring the entire clinical file that may be taken by the court, but will be returned later. The psychiatrist can also request to be deposed versus making a courtroom appearance, as a deposition will in general provide more convenience in location and scheduling. The psychiatrist will be sworn in and usually both attorneys will be present along with a court reporter. A deposition usually occurs outside of the courtroom, often at a lawyer's office. One lawyer may object to another lawyer's questions, but the psychiatrist will still be asked to fully answer. At a later time the lawyers may argue the objection in front of a judge and the testimony may be kept or stricken. The psychiatrist should be treated respectfully and allowed to have appropriate breaks. A copy of the deposition transcript may be requested for review and signature by the physician. This is usually helpful in correcting any misspellings of medical terms.

Case Illustration—Subpoena for Custody Case

Dr. Jones has worked with a family for approximately 1 year. The 6-year-old daughter, Anna, has been treated for an anxiety disorder while Dr. Jones also worked with the parents for some behavioral problems. Mrs. Smith was the parent that usually brought Anna to her appointments and Mr. Smith came for the initial evaluation and for two other sessions. The parents during this period have had a breakdown in their marriage and the mother has told Dr. Jones about numerous family problems that are affecting Anna that were discussed in the course of treatment. Dr. Jones has not seen the family for several months and then receives a phone call from Mrs. Smith stating that the parents have decided to divorce, and she asks Dr. Jones to write a letter to the court in support of her having full custody of Anna. She feels that Dr. Jones knows the problems in the family well and would be the best person to explain to the court why she would be the better primary parent for their daughter. Dr. Jones tries to explain that he does not feel comfortable complying with the request and feels that it would be unethical of him to do so. The mother then asks Dr. Jones if she can bring Anna in for a custody evaluation to allow Dr. Jones to feel comfortable writing the letter. Dr. Jones explains that it would be inappropriate for him to change roles from treating psychiatrist to forensic evaluator. Shortly thereafter, Dr. Jones is issued a subpoena duces tecum from Mrs. Smith's lawyer as he feels Dr. Jones' testimony will be helpful to her case. There is also a release of information included from both parents that will allow Dr. Jones to discuss protected health information. Dr. Jones reviews and discusses this request with his attorney. He then blocks his entire clinic day, gathers his case materials, and is in court on the scheduled date and time. During direct examination, the mother's attorney asks Dr. Jones if he thinks the father is emotionally capable of taking care of Anna alone if the parents

divorce, and what custody arrangement would be in the child's "best interests" in terms of visitations. Dr. Jones is later asked regarding the child's specific medical treatment rendered and what the long-term prognosis and plan would be for the patient. Dr. Jones has a release to discuss any specifics of the evaluation and treatment of Anna and is required to answer those questions to the best of his ability. However, regarding the earlier questions about the father's capability to raise Anna alone or what type of custody arrangement should be undertaken, Dr. Jones did not perform a custody evaluation and therefore does not have an opinion on those topics relating to Anna and informs the court of this through his answers.

EXPERT WITNESS

Child and adolescent psychiatrists may also contribute to judicial cases as expert witnesses. An expert witness is recognized by the court as being able to offer valuable information based on training and experience. Courts have long recognized that the information provided by individuals with special learning or knowledge can assist in deciding certain cases, such as child custody. A survey of judges and attorneys found that mental health issues were involved in one-third of juvenile cases (3). Unlike the fact witness, the expert witness can provide opinions that the court will treat with the same weight as facts in guiding its decision. Expert witnesses are permitted to testify about conclusions or opinions they have reached based on their professional skills and analysis, as well as provide information about their area of expertise. Serving as an authority for the court is a very different role for child and adolescent psychiatrists from involvement with the legal system on behalf of patients. It is critical for anyone serving as an expert witness to know the procedural, legal, and ethical differences in undertaking evaluations and providing reports for the court from clinical practice with patients and families.

Expert testimony is used in both civil and criminal litigation, two very different judicial settings. It is helpful for any expert appearing in either court to know the differences in the types of cases that are heard and the procedures used in them. Child and adolescent psychiatrists may be called to serve as expert witnesses in civil or family court for custody evaluations, termination of parental rights, or liability claim cases where no one has been charged with a crime. They may also be called to serve as expert witnesses in juvenile or adult criminal court for cases where a minor has been charged with an offense. While juvenile court differs in many aspects from adult criminal court, many of the processes and procedures are the same and the differences have decreased over time. In some states, juvenile courts are referred to as family courts, which can be confusing. Typically in civil or family courts, a plaintiff brings a claim against a defendant for the court to decide. The burden of proof is on the plaintiff and standard for decision is a preponderance of the evidence. In juvenile or adult criminal court, the district attorney brings charges against a

minor. The district attorney must meet a much higher standard of proof, where the evidence is beyond a reasonable doubt. In both civil and criminal litigation, the standard for medical expert testimony is a “reasonable medical certainty.” Cases in civil and criminal courts may be decided by a judge or by a jury.

Serving as an expert witness ethically requires the avoidance of any potential conflict of interest. A child and adolescent psychiatrist should not provide both therapy and expert testimony for anyone. The impartiality and objective position of the expert witness is undermined by having a therapeutic relationship with a plaintiff or defendant. Likewise, the ability to provide treatment is compromised by also offering expert testimony for any patient. Other potential conflicts of interests for expert witnesses include any outside relationships with any of the parties that create an interest in the outcome of a case, such as serving on the speaker’s panel for a drug company involved in a lawsuit.

It is also important to be familiar with the laws and rules concerning expert medical testimony as these may differ from state to state. Some states require licensure within that state in order to conduct an evaluation and testify (4). Some states require specific training or certification in order to perform certain types of forensic exams, such as competency evaluations. Further information and guidelines for conducting forensic evaluations are presented in the American Academy of Child and Adolescent Psychiatry Practice Parameter for Child and Adolescent Forensic Evaluations (5).

Process of Involvement

Child and adolescent psychiatrists are usually contacted directly by the court or by an attorney involved with a case to request expert testimony. The request might also come from a guardian ad litem appointed to represent a minor involved in court litigation or from child protective services pursuing an investigation of a child and family. Sometimes attorneys may have their clients make the initial call seeking expert testimony. This can be confusing as it may appear that the client is seeking clinical evaluation and care as a patient, rather than services from an expert witness. It is best if the initial contact is with the court or the attorneys requesting expert testimony in order to clarify not only the role but also the specific questions to be addressed in any evaluation, as well as details like scheduled trial date. The involvement of an expert witness in a legal case can be required and ordered by a judge, such as a juvenile disposition hearing, or it can be the choice of an attorney in preparing a case, such as a liability claim with emotional injuries for posttraumatic stress disorder. When it is ordered by a judge, it is usually as a court-appointed impartial expert. In this situation, the opposing parties before the court accept that there will be only one expert viewpoint providing testimony, rather than having their own separate or “dueling” experts present.

The first and most important step is to determine the question or questions that prompted the court or attorneys to seek expert testimony, just as in providing any mental health consultation. Sometimes the expectations on what child and adolescent psychiatry can answer or provide are unrealistic, and at other times a request is made for vague or unclear reasons. It is best to clarify the specific request for expert testimony from the start, in order to direct the evaluation and avoid unnecessary complications and confusion later on. This also helps to ascertain the level and extent of expertise required by the case and determines if the child and adolescent psychiatrist is qualified to comment as an expert. Being qualified as an expert for the court does not require that the child and adolescent psychiatrist be recognized as a national authority on the specific area in question, such as posttraumatic stress disorder in a liability claim, but that his or her background include sufficient experience to render a professional opinion. Outlining the specific question or questions for the potential expert will also provide information necessary to judge the relative merits of the case and if the psychiatrist is interested in undertaking the time and effort required to address the issues fully. Finally, along with the details of the parties involved, determining the questions for the expert permits the opportunity to uncover any potential conflicts of interests that might undermine or compromise an objective opinion.

It is also important to determine when and if any court dates have been set. Quite often, expert testimony is the last thing that is arranged as a case develops or a court hearing is scheduled. The psychiatrist must be very clear about the amount of time that will be needed to prepare any evaluation for the court and delays that can be expected in arranging appointments or receiving requested documents. Usually, allowances can be made for the requested evaluations in civil cases and attorneys can request a continuance, but juvenile and criminal courts do not have as much flexibility in their schedules. The child and adolescent psychiatrist should not feel pressured into undertaking cases when adequate time is not permitted to complete a thorough evaluation.

Contract and Payment

Following a decision to take on a forensic evaluation, it is best to have a letter of agreement or service contract outlining the type of evaluation to be performed, rates for fees and related expenses, and how payment will be received. Fees for forensic evaluation will vary from area to area but are typically higher than routine clinical psychiatric services because the nature of the work is more exacting and requires a certain level of expertise. The rates are usually set by the hour rather than a flat fee, since it is impossible to predict how much time any forensic evaluation might take. Charges are for all services, including direct clinical interview of involved parties, review of records, discussion with attorneys, preparation of report, and time spent in

deposition or court. There may also be other incurred expenses for travel with certain cases. It is unethical for experts to seek contingent reimbursement based on a percentage of any potential settlement in a civil case. This creates a vested interest in the outcome of the court's decision, undermining the objective position of the expert and compromising the integrity of any opinion expressed. Mental health insurance will not cover the expenses for forensic evaluation. Billing should be directed to those requesting the service, although some attorneys in civil cases may request that it go to the client. Sometimes court appointments for an impartial expert will also define who and what portion of the evaluation will be paid by parents involved in a custody hearing. With any court-ordered forensic evaluation, it is important to request a copy of the order. Quite often, the attorney will request a copy of the child and adolescent psychiatrist's curriculum vitae to be entered in support of the court's determination of expert status. It is important to have an updated curriculum vitae readily handy for court appearance and offer it even when it is not requested in advance.

Evaluation

Forensic evaluations are more complicated than routine clinical evaluations. It is not sufficient to determine if a mental disorder is present or not, but often whether it was present at a specific point in time and what relation it has to the question before the court. For example, the child and adolescent psychiatrist appearing as an expert must be able to say not only that a child has attention-deficit hyperactivity disorder, but also how it might have contributed to his specific behaviors that resulted in charges. For custody evaluations, it is insufficient to just identify the child's developmental needs; there must also be an assessment of both parents' abilities to meet those needs. Questions in a child abuse evaluation must be carefully fashioned to avoid leading the child and suggesting answers. Information must be collected in a fashion that will provide the basis for opinions within reasonable medical certainty.

Offering a psychiatric opinion on anyone requires a thorough evaluation of that individual by the child and adolescent psychiatrist. Interviews should be preceded by obtaining informed consent in which the purpose of the evaluation is made clear, especially that it will serve in preparing a report and who will see it. It is important to remember that those interviewed will probably be influenced in answering any questions by how they desire to see the case decided. Juvenile delinquents may minimize or conceal certain aspects of their life. Parents in custody disputes will want to present themselves favorably. The child and adolescent psychiatrist will want to take this into account and try to obtain the most complete picture by obtaining information from other sources, especially those that are more objective. For example, school records of behavior can be helpful in cases claiming psychiatric trauma, where it is critical to determine exactly when symptoms first appeared in

relation to the incident in question. Sometimes evaluations will require interviewing participants opposing each other in court who may not want to cooperate with an interview, such as parents involved in a custody dispute. In those cases, the child and adolescent psychiatrist should inform them that an opinion must be made with or without their participation and that it is in their interest to tell their side of the case.

It is very important to have access to and review of all materials relating to the questions presented by the evaluation. The child and adolescent psychiatrist conducting the examination may need the assistance of the court or attorneys as well as consent of parents in obtaining copies of previous evaluations, school reports, psychological testing, and medical records. Courts or attorneys requesting expert opinion can also be instrumental in arranging clinical interviews with all those necessary to the evaluation. Sometimes, additional consultations or testing may be indicated as part of a forensic evaluation. The recommendation for any referrals should be made to the court or attorney that arranged the initial evaluation.

Report

A written report is usually prepared and submitted prior to any testimony. It is useful to discuss the findings with the retaining attorney or judge prior to composing the report in order to be sure that all questions have been covered. The child and adolescent psychiatrist must not let such conversation influence his or her conclusions unless new facts are presented that had not been previously known. The report should clearly state the psychiatric opinion regarding the legal questions that have been asked and summarize the data on which that opinion is based. It should indicate that all information has been considered, both for and against, and that alternative conclusions have been ruled out. The format is similar to other psychiatric consultative evaluations, but must be more detailed. It should document all sources of information, list all those examined, with both the date and length of interviews, and all records reviewed. The text should be clear and understandable to lay readers, avoiding psychiatric jargon. Pejorative language should not be used. It is important to remember that the opposing side will review any report in detail and unwise language will be brought up in court. Information included in the body of the report should indicate the source, such as “the child described” or “the mother alleged.” It is useful to include direct quotations from those interviewed to illustrate specific points. The conclusion should offer a clear formulation from a psychiatric perspective and provide specific responses to all the legal issues raised by the request for expert opinion. If treatment is indicated, an appropriate plan should be outlined and for liability cases it should include the estimated length and costs of all necessary interventions. A well-prepared report sometimes results in reaching a settlement outside of court.

Testimony

The court procedures and advice presented in the section on treatment or fact witness apply to expert testimony as well. Attorneys retaining expert witnesses will most likely want to go over the material that will be presented in court and the questions likely to come up. Depositions are frequently used by attorneys to determine what type of evidence may be presented by an expert witness. Depositions are exactly like courtroom testimony and follow the same procedures in the sequence of examination. Attorneys will object to some questions, but unlike the court, the witness will answer the question and the judge will decide later if the objection will be sustained or overruled. Experts will receive a transcript of the deposition for authentication, and quite frequently it will need correction for medical terms. If followed by later courtroom testimony, statements made in the deposition may be used to challenge the consistency of expert opinion by answers that the expert has made in court.

The process of establishing qualifications may be more detailed if the child and adolescent psychiatrist is appearing for one side of the case and especially if opposing experts might testify. The opposing attorney may try to undermine the value of any subsequent opinion offered by indicating during establishment of qualifications that the child and adolescent psychiatrist is inexperienced, particularly in the areas in question, less worthy than the opposing side's expert, or is just an opinion for sale. The volume of forensic work done by the child and adolescent psychiatrist might be raised not only to challenge experience but also to demonstrate if that is the primary work activity and that the expert is merely a "hired gun."

The process and the advice for handling of direct, cross, redirect, and recross examinations in expert testimony are essentially the same as with fact witnesses. In addition to the qualifications of expertise, the testimony of a child and adolescent psychiatrist is expected to meet the general acceptance rule or Frye test, named after the case of *Frye v. United States* (6). This standard holds that a medical test, procedure, or disorder has been generally accepted in the scientific community. For example, describing a person as suffering from a particular syndrome is unlikely to be considered unless it is included in the *Diagnostic and Statistical Manual of the American Psychiatric Association*. A new standard for scientific opinion in federal cases was set by the U.S. Supreme Court's ruling in *Daubert v. Merrell Dow Pharmaceuticals, Inc.* (7). Unlike the *Frye* standard, *Daubert* states that the judge is the one to determine if the offered evidence is scientifically valid and that it will assist the court in understanding or determining facts relevant to the case. In addition, this assessment by the judge of expert opinion must be made prior to it being presented in court before a jury. Neuroscientific findings are increasingly being introduced as evidence in court cases. It is important to distinguish if the findings from certain tests, such as neuroimaging, refer to a certain disorder or population group in general or if they are regarding the specific individual case. Guidelines have

been developed in some instances for the introduction of neuroscientific evidence, such as neuroimaging (8). Sometimes opposing attorneys will object to expert testimony as "hearsay," as evidence based on the statements or experience of those other than the expert witness. Such evidence is permitted for expert witnesses, as the use of others' statements and experience gathered as part of clinical evaluation is a recognized practice in formulating psychiatric opinions. Opposing attorneys may also ask if the child and adolescent psychiatrist accepts or recognizes another professional as an expert in the field or a particular study, paper, or book as authoritative. This is usually in order to present information that may conflict or appear to contradict the evidence presented by the expert witness. It is important to maintain objectivity throughout testimony and avoid the appearance of personal bias. The expert is not a patient advocate in such situations, but presents psychiatric opinion and the data on which it is based.

Specialized Forensic Evaluation

The role and use of psychiatric expert testimony has increased over time and just as the body of knowledge has grown, so have the types of litigation used in court. The specialized topics of child abuse and child custody are handled in separate chapters in this volume. Juvenile justice and tort litigation represent, respectively, the oldest and newest areas of psychiatric expert opinion.

It is understandable that child and adolescent psychiatry be called on to evaluate the problems and needs of youthful offenders in disposition hearings. Child and adolescent psychiatry plays a crucial role in not only understanding antisocial behavior but also in assessing the frequent comorbid and contributing psychiatric disorders of delinquents (9). Beyond the assessment of juvenile delinquents and recommendations for treatment and rehabilitation, child and adolescent psychiatrists are called upon to perform a variety of other assessments for juvenile court. All states permit transfer or waiver of delinquency cases from juvenile to adult criminal court, usually for serious or violent offenses, and many require that a psychological evaluation be performed prior to doing this. The case of *Kent v. United States* (10) established due process and the standards for juvenile transfer. A transfer evaluation usually requires the child and adolescent psychiatrist to assess the amenability to intervention and developmental maturity of the youthful offender. In some cases, state laws require that a minor be tried for certain offenses in adult criminal court, but an appeal can be filed for a "reverse" waiver or transfer back to juvenile court. The same standards regarding maturity and amenability to treatment usually apply in those cases as well. As the juvenile court has become more like adult criminal court, questions have been raised regarding juvenile competency to stand trial and understanding of "Miranda" warning. Evaluation for competency to stand trial is especially relevant for adolescents, as research has shown that few below age 15

meet the adult standard (11). Unlike adults, adolescent incompetency to stand trial is typically due to developmental immaturity rather than mental defect, although adolescents may suffer from mental disorder that impairs cognitive capacity as well. While most states recognize the issue of juvenile competency to stand trial (12), few states have statutes that specify the standards for developmental incompetence, but this is rapidly changing (13). There are instruments that have been developed and tested in assessing an adolescent's competence to stand trial (14), but it will be important to determine what standards are used, if any, in a particular state.

Previously, the only liability cases involving child and adolescent psychiatric expert testimony were claims of malpractice or negligent care. Courts were reluctant to consider any claims for allegations of psychological trauma. The growing scientific understanding of posttraumatic stress disorder and public awareness have resulted in courts considering claims related to psychological trauma (15). Claims for compensation require not only that the child be suffering from posttraumatic stress disorder, but also that the incident in question be a major contributing cause for the symptoms.

Case Illustration—Disposition Hearing for Juvenile Case

Dr. Smith is contacted by the local juvenile court with a request to conduct a transfer evaluation of Jim, a 16-year-old boy currently held in juvenile detention following his arrest for armed robbery. A court hearing has been scheduled but the district attorney and judge agree to reschedule in order to allow time for the completion of the forensic evaluation. Dr. Smith agrees and arrangements are made for billing the court. A copy of the court order, arrest reports, probation record, and psychological testing are sent to Dr. Smith. He contacts the juvenile detention center and arranges times to interview both Jim and his mother, his legal guardian.

Dr. Smith reviews the records and learns that Jim was on probation for possession of a controlled substance (marijuana) when he was arrested for allegedly robbing a pizza delivery boy at gunpoint. No one was injured and apparently the gun was not loaded. He has one other recorded arrest for shoplifting (beer at a convenience store) when he was 13. Psychological testing reveals no current psychiatric complaints other than symptoms associated with his drug use. In addition, it notes that he would be considered competent to stand trial as an adult, although the psychologist expresses the opinion that Jim's needs would be better met by the juvenile court system.

On interview with Jim, Dr. Smith explains that she is preparing a report for the court as it considers sending his case for trial in adult criminal court. Jim understands and agrees to the interview. Jim describes feeling sad since his incarceration but does not have sufficient symptoms for a diagnosis of major depression. He admits to using alcohol and marijuana on almost a daily basis, having begun drinking at age 11 and smoking at age 12. He has drunk until he

passed out, but denies blackouts or other symptoms associated with alcohol use. He has had hallucinations associated with marijuana use. He has experimented with cocaine by snorting it on two occasions and has tried ecstasy several times but denies using or trying any other drugs. He also does not think that the marijuana that he uses is laced with other drugs but is not sure. He admits to arrests listed in his criminal record and to having stolen some money from his mother in order to pay for marijuana but denies other antisocial behavior, including physical fights, firesetting, vandalism, cruelty to animals, rape, and involvement with a gang. He states that he had been using both alcohol and marijuana with friends at the time that the pizza delivery boy arrived. He also remembers taking his friend's gun and threatening the delivery boy as a joke, although now he thinks what he did was stupid. His probation officer had made plans to refer him for drug treatment, but that had not taken place at the time of the incident. He also was noncompliant with his probation visits since he did not want to be found in violation with a positive drug screen. He was a student in ninth grade at the time of his arrest, having been held back for failing due to truancy and poor academic performance. He expresses a desire to get his GED and enter a trade school.

His mother also understands the purpose of the interview and agrees to answer Dr. Smith's questions. She reports that she and Jim's father were never married and that they amicably separated when Jim was 3 years old. His father has stayed involved with Jim, taking him every other weekend. She admits that both she and Jim's father have problems with drinking. She currently works evenings cleaning offices and says that it has been hard to supervise Jim. She corroborates Jim's description of his behavior and previous troubles with the law.

Dr. Smith considers that while Jim is mature, his offense was serious and previous probation has not contained his behavior, he does not have a pattern of violent offense and that there has never been a serious effort made to deal with drug use that is central to his antisocial behavior. She calls the district attorney to learn why the request for a transfer hearing was made. The district attorney points out the history of arrests, the appearance of threatening and potentially violent behavior, and that Jim will soon be 17 and beyond the scope of juvenile probation. Dr. Smith asks if the court has the option of deferred or concurrent sentencing, where Jim would be sent for drug treatment by court order and his progress reviewed at age 17, when he would either be released or sentenced as an adult. The district attorney said that was possible but did not know of treatment facilities that would take Jim. Dr. Smith then prepares a report for the court outlining her findings and opinion that Jim should not be transferred because there was no prior rehabilitation for his drug use and the lack of previous violent offenses. She recommends a facility that would accept Jim for drug treatment on court order. The court and district attorney accept Dr. Smith's report and recommendation at the hearing and she does not have to testify.

SUMMARY

There have been numerous changes in the judicial and legal systems in recent years that affect the role of the child and adolescent psychiatrist in court and how the courts deal with children and adolescents (16). The U.S. Supreme Court reviewed neuroscientific research on normal adolescent development in the recent decisions of *Roper v. Simmons* (17), *Graham v. Florida* (18), and *Miller v. Alabama* (19), which overturned the juvenile death penalty and juvenile life without parole (20). Changing laws, judicial rulings, and advancing psychiatric knowledge assure that there will be continued evolution of forensic child psychiatry. It is critical for any professional to keep abreast of these changes, even if forensic child psychiatry is not a part of their clinical practice. Practitioners may not choose to perform custody evaluations, but new laws and judicial decisions regarding custody will affect the children and families they care for. Understanding the judicial process improves the chances of being a more effective advocate for mental health, either as a fact or expert witness.

CHAPTER 7.4.2 ■ DIVORCE AND CHILD CUSTODY

MEGAN M. MROCZKOWSKI

INTRODUCTION

Approximately 50% of first marriages in the United States will end in divorce (1–4). Divorce therefore will affect approximately one million children annually in the United States; between 8% and 18% of divorces involve custody litigation (5,6). Thousands of children each year are at the epicenter of often protracted custody battles (1).

As a legal concept, "child custody" is different from "parental rights." Parental rights refers to the legal relationship between the parent and the child (7). This includes the parent's responsibility to provide financial support for the child, the parent's right to custody, to visit with the child, and to make educational, religious, or medical decisions for the child (7). In child custody cases, the court awards one or both parents (joint) legal and physical control of a minor (8). Legal custody refers to parental authority or decision making (9). Joint legal custody means both parents share major decision-making capacity such as education, medical care, and religion (9). Physical custody refers to the time children spend with each parent; joint physical custody indicates children spend time with both parents (9). Split custody refers to arrangements where each parent has sole physical custody of one child (9).

This chapter will highlight the history of child custody disputes, describe practice parameters for custody evaluations and elaborate on important current topics.

HISTORICAL CONTEXT

Beginning in ancient Rome and continuing into the 19th century, children were considered property of their fathers. Therefore, whenever there were custody disputes, children typically were awarded to the father (1). In the 1800s, the courts adopted the principle of *parens patriae,* a moral and legal duty to protect citizens unable to protect themselves. Philosophy evolved into psychology and child development, and the importance of childhood experiences became paramount. Courts followed suit by increasing concern about protecting family members. Courts in Great Britain and the United States became more involved in family disputes, especially when children were involved or at risk (10).

There has been an evolution of models used by judges in custody disputes (11). Psychoanalytic theories highlighting the importance of the mother–infant bond led to the "tender years" doctrine (11). This judicial presumption held that the mother–infant bond is inviolable (11). Barring cases of maternal unfitness, courts awarded custody of young children to the mother (11). The "tender years" doctrine prevailed

well into the 20th century.

Within the last century, the prevailing legal test for child custody in all states is the "best interests of the child" (12). This doctrine, first described by Justice Benjamin Cordoza in *Finlay v. Finlay* (12), encompasses the parent–child relationship, the validity of each parent's plans for the child, and puts emphasis on protecting the child's maintenance of bonds with attachment figures (13). It is argued that the benefit of the "best interests of the child" doctrine is to place the judicial focus on the children, making them paramount in the process (1). The concept exemplifies *parens patriae.* Contrary to this, some argue that the use of the word "best" creates an impression that there is a good solution to a particular custody debate, and that the court is responsible for finding this. It has been argued that the terminology should perhaps be changed to "least detrimental alternative," (14) which suggests that all children in custody disputes sustain harm at some level and the best solution is that which causes the least amount of harm (1). Of note, no states have adopted this construct.

The Changing American Family

Same-Sex Marriage

The concept of the American family has grown and evolved. In 2003, in *Goodridge v. Department of Public Health,* Massachusetts became the first state to legalize same-sex marriage (15). In 2013, the U.S. Supreme Court found key provisions of the Defense of Marriage Act (DOMA) unconstitutional (16).

In 2015, the U.S. Supreme Court, in *Obergefell v. Hodges,* extended the right for same-sex couples to marry (17). More specifically, the Court ruled that state bans on same-sex marriage and the refusal to recognize same-sex marriages from another state were both unconstitutional based on the rights of due process and equal protection (17). This case allowed for spouses of the same gender to have the same rights as legally married heterosexual opposite-sex couples including tax relief, emergency medical decision-making power, access to domestic relations laws, spousal benefits (including workers' compensation), inheritance rights, and spousal termination privilege, the ability to divorce (17).

Embryonic Technologies

Recent advances in reproductive endocrinology, including in vitro fertilization (IVF), gamete intra-fallopian transfer, and surrogate embryo transfer, have assisted many couples and individuals achieve pregnancy who may have otherwise been unable to do so (8). During IVF, mature eggs are retrieved from the woman's ovaries, fertilized by sperm in a laboratory, and are implanted into the woman's uterus (18). In gamete

intra-fallopian transfer, the sperm and oocytes are directly transferred into the fallopian tube (19). Surrogate embryo transfer involves implanting an embryo into the uterus of a surrogate.

Advances in this technology have led to legal and ethical dilemmas, many of which are not yet covered by state laws. One area of ethical and legal debate is between genetic mother versus gestational mother. In this scenario, one mother donates her egg for fertilization through IVF to another woman for gestation in her uterus. Each of the two women makes a biologic contribution to the creation of the new human life. In *Johnson v. Calvert* (20), the gestational mother filed suit for parental rights of the child that she bore for another couple (8). The court found in favor of the biologic mother and likened the surrogate to a foster parent, standing in for a parent temporarily unable to care for her child.

Surrogacy, impregnation by artificial insemination with the sperm of the husband of a childless couple, carries with it ethical and legal questions. *In Re Baby M* (21,23) the first well-known case of its type, which received notoriety in the lay press, highlights one dilemma. In this case, the surrogate changed her mind after delivering the child and refused to surrender the child (8,23). The court found there was a contract between the parties that was legally enforceable. The surrogate mother appealed her case to the New Jersey Supreme Court, declaring that a surrogacy contract undermines the dignity of human life and cannot be enforced (8). The New Jersey Supreme Court unanimously reversed and invalidated the surrogacy contract, granting custody to the biologic father, with visitation rights to the surrogate (8).

In *Jones v. York* (22), the court ruled that a couple has the right to possession of their embryo (8,22). The Joneses kept one frozen embryo at an IVF program in Norfolk, VA, and when they moved to California, requested the program transport the embryo to an IVF program in CA. The Norfolk program refused to release the embryo citing the signed consent form, legal liability risk, and the demeaning nature of mailing a human embryo. The court ruled for the Joneses and described the embryo as an object rather than a human being. Thus, the embryo was considered property to be returned (8,22).

In *Davis v. Davis* (21,23) a couple cryopreserved seven embryos for possible future use. The couple divorced and the question arose over the possession of the embryos. The husband sought to prevent the release of the embryos to anyone, including his ex-wife, and the wife sought to have the child with the embryos. The court ruled that the seven frozen embryos were "human beings existing as embryos" whose best interests necessitated "they be available for implantation." The judge awarded the wife with the embryos for implantation but reserved the question of child support, custody, and visitation rights until the children were born (8,21). Ms. Davis remarried in Florida and decided to give the embryos for adoption to a childless mother. The husband filed suit and on appeal the higher court reversed and

ruled the couple shared an interest in the embryos and in the event they could not agree with what to do, the embryos should remain frozen (8,21).

Fathers

In comparison to issues involving reproductive technologies, the law is clearer regarding the rights of fathers. In *Stanley v. Illinois* (24), Mr. Peter Stanley lived with Ms. Joan Stanley intermittently for 18 years, during which time they had three children. Under Illinois state law, upon the death of a mother, children of unwed fathers become wards of the state. When Ms. Stanley died, the children were declared wards of the state, though their father was never shown to be an unfit parent. When custody of a child is challenged, parents are permitted a hearing in which to demonstrate he or she is a fit parent. The U.S. Supreme Court held that by denying Mr. Stanley a hearing as to his parental fitness, Illinois denied him equal protection of laws under the Fourteenth Amendment (25). The Fourteenth Amendment of the U.S. Constitution forbids states from "denying any person life, liberty or property, without due process of law" or to "deny to any person within its jurisdiction the equal protection of the laws" (26).

In *Michael H. v. Gerald D.* (27), the mother was having an extramarital affair and conceived a child (27). The biologic father filed a "filiation action" in California Superior Court to establish both his paternity and visitation rights. The U.S. Supreme Court held that the genetic father has no legal rights if he became a father through adultery. When a child is born during a marriage, the father is presumed to be the legal father, regardless of the source of the sperm (8,27).

Rights of Third Parties

In 25 states there is statutory law protecting the rights of third parties to maintain a relationship with a child (8). The language of these statutes typically uses the term "significant relationship" in lieu of more specific groups, such as grandparents, stepparents, etc. (8,28).

One example of stepparent's rights is *In Re Ewing* (1974). The court granted custody to the stepfather, who had financially supported the children and with whom the children had lived for 3 years prior to their mother's death instead of their biologic father, with whom they had no contact. Another example of third person rights, in this case grandparents' visitation, is found in *Troxel v. Granville* (29). Following the death of their son, the paternal grandparents filed suit for the right to visit their grandchildren. The U.S. Supreme Court held that the Washington statute, which allows any person to petition for a court-ordered right to see a child over the custodial parent's objection, was unconstitutional. The Court held that even if such visitation was found to be in the child's best interest, it interfered with the fundamental right of a parent to rear his or her children (29).

Divorce—An Update

Short-Term

Conflict within the marriage is a more important predictor of child adjustment than is divorce or postdivorce conflict (30,31). There are three central explanations for why divorce has a negative impact on children's lives: parental absence, economic disadvantage, and family conflict (32). Divorce is associated with a decrease in both quantity and quality of contact between children and their noncustodial parents (32–34). One meta-analysis sought to summarize the effects of parental divorce on children. This study found that compared to children from intact families, children of divorce experience lower levels of well-being, though the effect sizes are weak (32).

Developmental factors dictate how children and adolescents manifest their distress at the time of divorce (35–38). Preschool children may experience regression, intensified anxiety and fears, sleep disturbances, and increased aggression. Middle school–aged children may experience a sense of powerlessness, anxiety, and loneliness. They may also struggle with feelings of responsibility for the divorce, conflicts of loyalty between the parents, and have fantasies of reconciliation. Their school performance and peer relationships may also be negatively affected. Adolescents may experience acute depression, intense anger, and anxiety about their own future relationships. They may also withdraw socially and accelerate their separation and individuation process from the family. In general, this acute response diminishes or disappears over a period of 1 to 2 years (39).

Parental divorce has been shown to be related to an increase in boy's externalizing behaviors in school, especially if the divorce was during middle school (40). Girls externalizing behavior problem trajectories were not affected by parental divorce, regardless of when the divorce occurred (40). Divorce occurring from kindergarten to grade 5 was associated with more adverse effects on internalizing and externalizing problems than divorce occurring between grades 6 and 10 (41). However, divorce occurring between grades 6 and 10 was associated with more adverse effects on grades in school (41).

Long-Term

Dr. Judith Wallerstein conducted a 25-year longitudinal study on the effects of divorce on children (42). She and her colleagues found divorce is a cumulative experience for the child and its impact increases over time and may superimpose a series of difficult tasks on top of normal developmental milestones. There have been several critiques of this study. For instance, it was argued this was not a rigorous study as it included a nonrandom sample, without a comparison group of separating families from the general population of parents with children of similar age (43,44).

Additionally, the sample was not a representative sample as it was comprised of mostly white, well-educated parents, a significant proportion of which had psychological problems (43).

One study found divorce was associated with declines in reading scores, positive approach to learning, interpersonal skills, and self-control, and associated with increases in internalizing problems and externalizing problems (45). These results were consistent for younger children and adolescents.

Marital conflict is associated with more depression and psychological disorders in young adults (32). Numerous studies have described that divorced children have been reported to be more aggressive and impulsive and more likely to engage in antisocial behaviors compared to age-matched controls of never-divorced children (46). Divorced children are more likely to use alcohol, cigarettes, and marijuana compared to never-divorced children (46). This is thought to be related to more reliance on peer groups that use substances, less effective coping skills, and impaired parental monitoring (46). Divorce has been associated with lower academic achievement in children, though the effect size is small when socioeconomic controls are utilized (46). It has also been described that children in single-parent families are at higher risk for video game addiction (47).

No “Good” Time

There is no good or ideal time to divorce for children. Rather, there is research that shows the well-being of the children is positively correlated with the postdivorce psychological adjustment of the custodial parent, low parental conflict, and financial security of the mother (48,49). Social functioning of the children is positively associated with custodial mother’s reports of extended family support (46). Furthermore, the quality of the relationship between the child and both parents is positively associated with the child’s adjustment (49). Several studies show that the well-being of children of divorce improve over time; more specifically, the behavior of boys and girls improved within 2 years following divorce (48).

Etiologies of Divorce

The National Survey of Families and Households (NSFH), a nationally representative sample of adults and their spouses or cohabitating partners, examined the effects of divorce on the couple’s attitudes (50). It was found that husbands’, but not wives’ perceived disagreements was associated with a higher chance of divorce; the couples’ marital happiness strongly mediates the effects of the husbands’ dissatisfaction (50). Physical violence was found to be the main hardship that causes divorce (50). The findings in this study suggested that relationship instability arises from possibly explosive fights in which very unhappy, dissatisfied partners do not find mutually satisfying solutions (50).

Ways to Avoid Litigation

Collaborative Family Law

In 1990, Mr. Stuart Webb, an attorney in Minnesota, founded a term for a process of alternative dispute resolution called collaborative family law (CFL) (45). CFL consists of attorneys working with couples in four-way settlement conferences in an attempt to settle the divorce amicably and without resorting to the adversarial process in court (51). Prior to settlement conferences, the parties all agree to the basic tenets of collaborative law: to negotiate openly and honestly, motivated by the avoidance of disputes that may arise during discovery (51). Ms. Pauline Tesler, an attorney in California, worked similarly on CFL in San Francisco (51). Collaborative law is also unique in its use of a "participation agreement," a binding contract between counsel and the parties describing collaborative law and encouraging good faith negotiations to avoid litigation (52).

Collaborative law is not without criticism (53). Critics argue that the disqualification requirement is unethical and a violation of the American Bar Association (ABA) Model Rule of Professional Conduct 1.16 because it allows attorneys to withdraw their representation when litigation becomes necessary, which may be when their clients need their help the most (53). Critics also argue that should the collaborative break down, clients will spend more money than they would have in other forms of dispute resolution (53).

Mediation

Mediation provides divorcing couples with a second alternative to the adversarial process in court (46). Research in five countries over two decades has led to the conclusion that custody mediation should be offered widely and should be considered prior to proceeding to court (46). Satisfaction with the process is high, even among those who fail to reach an agreement (46). The outcomes of two types of family mediation, child-focused mediation (focusing on the child's needs without direct involvement of the child) and child-inclusive mediation (includes child interviews), were studied (54). Compared to those in the child-focused mediation, those in child-inclusive mediation had less relitigation (54). Custody mediation leads to settlements in 50% to 85% of cases, and leads to more joint legal custody agreements than litigated cases (55). Some studies have shown that mediation is associated with less postdivorce conflict along with more parental cooperation and communication about children, than parents in adversarial custody disputes (46). Mediation is frequently more efficient and less costly than traditional litigation (52).

There are arguments against mediation (53). Mediation focuses the dispute resolution process on one person, the mediator, instead of the parties and attorneys

working together (53). Mediators often emphasize the statutory, common law, and local origins of the suggestions made to clients, which may pressure them to settle due to feeling threatened or overwhelmed (53). Should parties settle through mediation for the wrong reasons, they may pursue additional legal action in the future (53).

Settlement Between Parties

Approximately 90% of child custody disputes are settled out of court (5,56). One survey assessed the perspectives of 59 attorneys regarding child custody evaluations completed by mental health professionals (56). The attorneys were asked their opinions about factors that prompted custody evaluations, expectations regarding evaluation procedures, utility of the resultant report, and the impact of evaluations on litigation. Findings indicate that attorneys are most likely to seek child custody evaluations in the context of questions of parental fitness or allegations of physical or sexual abuse. Attorneys reported they expect a comprehensive evaluation and report. Custody evaluations play a significant role in the decision of whether to negotiate a settlement or proceed to trial (56).

Postdivorce Programs

There are many divorce education programs connected to courts, some of which are mandated by state or local law (46). These programs utilize research about divorce, parental conduct and child adjustment, and some also have sessions for children (46). Typical objectives of divorce education programs include information for parents about how children respond to separation and divorce, information about the potential ill-effects of high conflict divorce on children, illustrate positive parenting responses to help children adapt to divorce, and describing a child's need for continuing relationship with both parents (46). Programs encompassing multimedia approaches including videos, skill-building demonstrations and exercises, discussion, handouts, and some didactics were found to be more effective than single format programs (46).

Examples of postdivorce programs include the PEACE Program, KIDS Program, and Children First (57). One review found limited evidence that these programs achieve their stated goals of improving the quantity of noncustodial parent contact, reducing conflict between parents, improving co-parenting, reducing relitigation, or improving outcomes for children (57). The lack of evidence of the programs effects is due to methodologic limitations in the evaluations in that there have not been rigorous evaluations of these programs (57).

Custody Disputes

Why They Happen

Ten percent of divorces involve custody litigation (1). It is important to understand the historical underpinnings of the divorce (58). It has been noted that the adversarial process exacerbates the conditions that create risk for children, and in the process, often undermines efforts of parents to maintain protective conditions for their children following divorce (59). The central failing of the adversarial process in custody disputes are the inherent mechanisms and practices that escalate conflict, decrease the possibility of civil communication between parents, highlight the win–lose atmosphere, and encourages bitterness and irresponsibility of parents (59). Legal strategies focused on winning a custody dispute start early in the adversarial process, and may include parents advised not to speak to the other parent, to search or exaggerate memories of damaging information to build their case (59).

Stress on Parents and Children

Custody disputes can have damaging effects on both parents and children (59). Several studies support the view that children may wish to for their input and concerns to be heard during the divorce process (60).

Positive Effects of Divorce

One study described the positive effects of divorce as perceived by children (61). These included happier mother, happier father, closer relationships with both parents and siblings, and a greater appreciation for siblings (61).

Special Issues in Custody Disputes

Same-Sex Divorce

There are no differences in the development of gender identity and gender role as a function of the sexual orientation of the parent (62). Furthermore, it has not been found that children reared by homosexual parents proportionately identify more as homosexual (63). It is consistently found that children of homosexual parents have no significant differences in separation-individuation, behavior problems, self-concept, moral judgment, school adjustment, or social relationships compared to those with heterosexual parents (64). One recent national, longitudinal, population-based sample described that adult children of same-sex parents were more similar than different from those of heterosexual parents (65). Adult children of same-sex couples were less likely to practice religion and had less contact with their parents than children of heterosexual parents (65). Research findings provide no justification for limiting custody or visitation by homosexual parents (64).

Long-Distance Parenting

As of 2015, at least 37 states had statutes regarding relocation of children following divorce (66). In *Tropea v. Tropea* (67), New York's Court of Appeals, the state's highest court, held "that each relocation request must be considered on its own merits with due consideration of all the relevant facts and circumstances and with predominant emphasis being placed on what outcome is most likely to serve the best interests of the child" (67). Rather than applying the three-step meaningful access exceptional-circumstances analysis, this court held that each relocation request should be based solely on the best interests of the child (67). *In re Marriage of LaMusga* (68), the California Supreme Court held that in parental relocation, the noncustodial parent who opposes the relocation has the initial burden of proof of showing that the relocation would cause detriment to the child (68).

Allegations of Domestic Violence

Child custody decision making in the context of alleged domestic violence is an area both controversial and unpredictable (69,70). The U.S. Department of Justice Office on Violence Against Women (OVW) work led to the National Child Custody Differentiation Project (69). The project's main goals included identifying domestic abuse through screening, understanding the context of the abuse, understanding the implications of abuse, and accounting for the abuse in custody-related decisions (69).

Studies have indicated high rates of intimate-partner violence, ranging from 25% to 50%, in samples of high-conflict divorce (71). Intimate partner violence adds a complicated concern to child custody disputes. Guidance has been provided by experts in the field about assessment, interventions, and visitation centers (72–74). New York Domestic Relations Law 240 requires courts making custody decisions "must consider the effect of such [proven] domestic violence upon the best interests of the child" (75).

Allegations of Sexual Abuse

Child sexual abuse allegations can occur with child custody disputes (75–78). Research has suggested that 50% of allegations made in child custody disputes are unsubstantiated (79,80). There are some best practices that have been described by experts in the area (81). Specifically, when assessing allegations of child sexual abuse, the forensic psychiatrist should gather information from multiple sources, consider all reasonable hypotheses that could explain each facet of the allegation, consider the context of the allegation, and examine and present all evidence that the allegation is true and all evidence that the allegation is false (81).

One Canadian study described that 12% of child abuse investigations were in the context of child custody disputes (82). This study found that 5% of all investigations

in child custody disputes involved allegations of sexual abuse; this was not statistically significant from those not involved in a child custody dispute (82).

Drug Use

It is imperative for a child custody evaluator to explore whether either parent abuses drugs or alcohol (1). It is incumbent upon the child custody evaluator to determine the impact of the possible substance abuse on the child (1).

Mental Illness in Parent

A common issue may arise when one parent has a mental illness. The diagnosis itself should not impact the child custody decision; rather, the effect of the psychiatric illness on the parent–
child relationship should be explored along with whether the mentally ill parent has insight into his or her illness and is responsible with treatment (1,83). In *Jaffe v. Redmond,* the U.S. Supreme Court held that the Federal Rule of Evidence 501 protects the conversations between a therapist and patient, thereby recognizing a "psychotherapist–patient privilege" (84). Psychotherapy treatment records may be disclosed in a child custody proceeding if the person holding the right to confidentiality, or privilege, voluntarily authorizes disclosure (85). The Health Insurance Portability and Accountability Act (HIPAA) mandates that the authorization for release of protected health information, for example, psychotherapy treatment records, must be voluntary (86).

Child with Special Needs

It is imperative that a child custody evaluator explore the child's physical and mental health (1). The clinician must assess each parent's ability to understand and provide recommended treatment for the child's disorder (1). Examples may include a child with a psychiatric diagnosis such as attention-deficit hyperactivity disorder (ADHD), or neurologic or physical disabilities. The clinician should assess how well each parent can provide specialized care, such as at-home environmental, therapeutic, and behavioral interventions along with ensuring additional services, such as occupational and speech therapy, are obtained if warranted (1).

Grandparent's Rights

The best-interest doctrine is a gender-neutral, child-centered model for decisions of child custody. The landmark case, *Painter v. Bannister* (87), highlights the issue of a custody dispute between a biologic father, Mr. Painter, and biologic maternal grandparents, Mr. and Mrs. Bannister. Immediately following the death of the biologic mother and one child, Mr. Painter, who lived in California, asked his wife's

parents, the Bannisters, to care for the surviving child in their home in Iowa. When the biologic father remarried, he sought to return his child to his custody, but his maternal grandparents declined (84). The Iowa Supreme Court awarded custody to the maternal grandparents (87).

Relocation

Many divorced parents seek the court's permission to move with their children away from the other parent (88–90). Relocations may result in substantially less contact with the noncustodial parent. Older children who move following divorce have been shown to have higher levels of maladjustment (91).

Several cases illustrate various courts' differing decisions on this topic. In *Rains v. Rains* (92), the Michigan Court of Appeals held that the party requesting the change of domicile has the burden of establishing by a preponderance of the evidence that the change is warranted (92). The court considered whether the legal residence change had the capacity to improve the quality of life of both the child and relocating parent, the degree to which each parent had complied and utilized his or her time under the current parenting agreement, the degree to which the move would allow continued relationships with both parents, the extent to which the parent opposing the move was motivated by a financial desire to uphold child support, and whether there is a presence of domestic violence (92). In *Tropea v. Tropea* (93), the New York State Court of Appeals, the state's highest court, held that the best interest of the child standard should hold in relocation cases (93).

In contrast to these two cases, the California case, *In re Marriage of Burgess* (94), replaced the best interests of the child standard. In this case, the parent who opposed the move must prove the children would be harmed if they relocated (94). In essence, the best interests if the child standard was replaced by the best interests of the custodial parent standard (88,94). Similarly, in *Baures v. Lewis* (95), the New Jersey Supreme Court held that parents wishing to move must demonstrate good faith and that the move will be in the child's best interests (88,95).

The following factors have been proposed to be considered when determining whether relocation should be permitted (88). First the psychological adjustment and parenting capacities of relocating parents, the psychological adjustment and parenting skills of the nonmoving parents, conflict between parents, economic situation following relocation, and the distance between parents following relocation (88).

Parental Kidnapping

Uniform Child Custody Jurisdiction Act. Parental kidnapping is defined as removal, concealment, detention, or retention of a child from the other parent (96). Before 1968, State courts in the United States could exercise jurisdiction over a child custody case based on the child's physical presence in the state (97). Courts would

freely modify sister States' custody orders because the U.S. Supreme Court had never settled the question of whether the Full Faith and Credit Clause of the U.S. Constitution applied to custody decrees, meaning one state must respect the custody decision of another state (95,96). This fostered child abduction and forum shopping (97). The Uniform Child Custody Jurisdiction Act (UCCJA) of 1968 governed the jurisdiction in initial child custody determinations and required States to enforce, not modify, sister States' orders (97,98). The UCCJA established four jurisdictional grounds: home state (child has lived for at least 6 months), significant connection, emergency, and vacuum (applies when no other jurisdictional basis exists (97)). The Uniform Child-Custody Jurisdiction and Enforcement Act (UCCJEA) of 1997, replaced the UCCJA (97). The UCCJEA governs the State courts' jurisdiction to make or modify child custody and visitation orders (97).

Parental Kidnapping Prevention Act. The Federal Parental Kidnapping Prevention Act (PKPA) was signed into law in 1980 to address problems of custody jurisdiction (99). The act provides for full faith and credit for child custody determinations made by the proper state (96,99). The PKPA was drafted to act as a tiebreaker when two states claim they have jurisdiction in a child custody or parental abduction case (96,99). State courts that exercise jurisdiction consistently with the criteria in PKPA are entitled under Federal law to have their custody and visitation orders given full faith and credit in other States (97). Both the UCCJA and PKPA were enacted to prevent jurisdictional gridlock in custody and child abduction cases and to facilitate the interstate enforcement of child custody decisions (96). The UCCJEA, law in all states except Massachusetts, has solved most of the jurisdictional conflicts and ambiguities that remained under UCCJA and PKPA (100).

The Hague Convention and the International Child Abduction Remedies Act. The Hague Convention was signed by the United States in 1981, ratified by Congress in 1986, and implementing legislation was passed in 1988 (101). The Hague Convention accomplishes the same purpose as UCCJA and PKPA on an international level (96,102). The purpose of The Hague Convention is to allow for the prompt return of the parentally abducted or wrongfully retained child to the country of their "habitual residence" (95,101). The International Child Abduction Remedies Act (ICARA) is the implementing statute of the Hague Convention within the United States (103).

Impact on Children. In all 50 states and the District of Columbia, parental child abduction is a crime (104). One study demonstrated parental abduction was associated with an increase in children's conduct problems, learning problems, psychosomatic diagnoses, and anxiety (105,106). Another study reported a high level of posttraumatic stress disorder (PTSD) in children who had been abducted (107). A study of children after abduction found that most reported satisfactory adjustment

though a high proportion received mental health services (106). A more recent study corroborates these findings (104). More specifically, abductees were found to have trouble sleeping and concentrating, trouble recalling important aspects of the abduction, trouble making and keeping friends, and loss of trust in the opposite sex (104).

Parental Alienation

In the process of a high-conflict separation or divorce, a child may ally him- or herself strongly with one parent while rejecting another parent. This has been described as parental alienation, a child's strong alignment with one parent without legitimate justification (108). This controversial concept, and the concept of parental alienation syndrome were proposed, but ultimately not included in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) and the *International Classification of Diseases,* Eleventh Edition (ICD-11) (108). Scholars have debated over whether such a syndrome exists, and use of the term has engendered considerable criticism and controversy (109,110).

The Custody Evaluation

Guidelines for evaluating child custody disputes have been published. The American Academy of Child and Adolescent Psychiatry (AACAP) has published Practice Parameters for Child Custody Evaluations (1). The American Academy of Psychiatry and the Law, The American Psychological Association (5,111), The American Psychiatric Association (112), The American Association of Family and Conciliation Courts (113), have all published practice parameters. Several states also have published their own guidelines for custody evaluations (114–123). In addition to these professional organizations and states, several mental health practitioners have also published guidelines (124,125).

The average child custody evaluation takes approximately 21 hours, including time spent completing the following: review of materials, interviews of all relevant parties, observations, collateral contacts, report writing, and sometimes testimony in court (126). The evaluation is composed of several phases: preparing strategy, performing the clinical evaluation, writing the report, and at times, testifying in court (126). The evaluation itself may take 1 to 3 months and it may be over a year before the court hears the case (1).

Referral Process

Section 405 of the Uniform Marriage and Divorce Act states that a court may order a custody evaluation if "a parent or the child's custodian so requests" (127). In several states, for example, New York and California, appointments are court-ordered

(1,128). A referral from noncustodial parent, requested while he or she has visitation, should be refused (1). It is both unethical and usually illegal to interview a child without permission of the custodial parent, unless court-appointed and ordered by the judge (1). It is important to accept only cases if the evaluator is court-appointed or agreed-upon by both parties (1). It is better, however, to be court-appointed to come under the court's immunity. The clinician should clarify all questions requested by the judge to determine whether he or she can provide an opinion (1). The fee should cover all clinical interviews, document reviews, consultations by phone, and report writing (1).

Evaluation Structure

The evaluator should request documents, including medical, educational, and psychiatric records (1). In addition to interviewing the parents, children, each parent with the child(ren), and stepparents or significant others who one of the litigants is planning to marry, it may also be helpful, in certain circumstances, to interview extended family, nannies, school teachers, or babysitters (1,129). It is paramount that the clinician inform all interviewees that due to the forensic nature of the evaluation, the interviewee automatically waives their rights to confidentiality (keeping protected health information private) and privilege (the right to keep information private from the court) (1). It may also be helpful to visit one or both homes and to contact school staff and or mental health providers, with consent from parents (1,85).

Interview Structure

The clinician may consider meeting with both parents together, if they are willing, or with each separately (1). During the first session, it is important to explain to each parent the nature of the evaluation. During the next session, or the end of the first, the evaluator should ask what they are seeking from the court as if the clinician had no prior knowledge of the case (1). It is important to obtain a description of each parent's history including family, social, and psychiatric history, each parent's description of the marriage and separation, each parent's perception of his or her relationship with the children, each parent's understanding of and sensitivity to any special needs of the children, and each parent's specific plans for the future if custody is awarded (1). If there is mental illness in either or both parents, it should be fully described as well as its impact on the children.

Interviewing the Child(ren)

It is important to interview the children early in the course of the evaluation. Each child should be seen at least one or two times alone, and should be brought by each parent at least once (1). It may be best to see all siblings together for the first session

with each parent for support and to alleviate anxiety (1). Children and parents should be interviewed together, and this should be as unstructured as possible (1).

The Written Report

In preparing the child custody report, the clinician considers a number of factors when making his or her final recommendations. These include: continuity, preference, attachment, sensitivity and respect, parent–child gender, and level of conflict between parents and the impact on the child (1). Reports should be concise but detailed, and without any technical jargon, unless it is explained (1). There should be a list of dates and times of all interview sessions along with a list of all collateral sources of information, including phone calls and review of legal documents (1). The report should contain a "Conclusions and Recommendations" section with the formulation of the case and detailed recommendations as per the order of appointment on custody, visitation, and other recommendations, such as psychotherapy (1).

Testimony

Parents may reach a settlement before, during or after the evaluation, or after the expert's testimony (1). The evaluator should bring all materials to trial (1).

Evaluator Opinions on Child Custody

Forensic assessments in custody disputes often have tremendous weight and can affect the trajectory of the litigation and ultimately the child's life (130). Studies have shown that clinicians' involvement in child custody cases has a high perceived value; courts follow an expert's custody recommendation up to 90% of the time (131–133). There is variability in judges: some judges may request the forensic examiner opine on the ultimate question of custody while others may prefer the forensic evaluator refrain from such opinions.

It has been argued that experts should not testify on the ultimate issue in civil cases, such as custody (132). Tippins et al. argue that evaluators' conclusions on issue of child custody should not be permitted. He argues such opinions exceed the boundaries of the empirical knowledge base of the mental health profession and they implicitly misrepresent the limits of that knowledge base (131). Tippins recommends that clinicians with adequate forensic training can provide very useful and helpful information to the court. For example, admissions regarding disputed questions, descriptions of parenting behavior, and data-based inferences on parenting skills (131). He recommends psychologists and psychiatrists include warnings on reports about the limitations in the capacity to predict the best custody plan. Further, he advises that judges should order specific statements precluding the expert witness

from addressing the ultimate issue (131).

The Future

Technologic innovation and sociocultural changes have impacted family structure and functioning, and have driven changes in clinical practice and the law. Child custody cases have evolved significantly from children being considered property of their father to the current "best interests of the child" standard. With further advances in reproductive endocrinology and marriage rights, case law and legislature regarding child custody will further evolve.

CHAPTER 7.4.3 ■ ADOPTION

RACHEL MARGARET ANN BROWN

Adoption refers to a formal action in which an adult assumes permanent, primary, legal, and other parental responsibility for another person, usually a minor, from the biologic or legal parents. The most recent data available, from 2007 to 2008, indicate that approximately 136,000 children were adopted annually in the United States (1). Despite the psychological significance of the event, it is likely that most of the participants involved in most adoptions never encounter child and adolescent psychiatrists. As our professional pathways intersect the lives of people involved in the adoption process at different places (but almost always at times when there are problems), we see only the fragmented parts of a complex and multifaceted picture. This chapter is directed at providing a cohesive overview of adoption.

HISTORICAL ASPECTS OF ADOPTION

Adoption is an ancient practice, although not a universal one. It was codified more than 4,000 years ago by the Babylonians, and is described in the Bible, for example, in the adoption of Moses by the daughter of Pharaoh. The ancient Romans practiced both the adoption of children and that of adults, in order to provide a suitable heir for the family. Similar practices, with similar motivation, are described in China, in ancient Egypt, Greece, and in the Polynesian societies of Tahiti and Hawaii. Originally, adoption was designed to benefit the adopter, by providing them with a successor, someone to carry out rituals after their death, someone to work on their behalf and support them, or someone to cement a critical power alliance.

Informal adoption has probably always been part of modern American society. In the 19th century, it existed alongside other ways of taking care of orphaned children, including the "boarding out" in foster care of babies from almshouses, the system of apprenticing and indenturing impoverished children, and the practice of sending homeless children from the Northeast by orphan trains to work in farming communities in the Midwest. The world's first adoption statute was implemented by the Commonwealth of Massachusetts in 1851. During the first half of the 20th century, most adoptions in the United States were still informal, and did not guarantee confidentiality for any of the parties. Adoptions were frequently accompanied by the stigma of illegitimacy and fear of the inheritance of defective genes. Throughout the 20th century up to the present day, the states, and later the federal government, have steadily formalized the practice of adoption. Statute now governs the practice, even when it is independently organized by the physicians, lawyers, and families involved. Significant social change has affected the numbers and context in which adoption now takes place. The private adoption of infants was a fairly common practice prior

to 1970, when reliable contraception was unavailable and single mothers unsupported and stigmatized. Many unmarried mothers chose (or were pressured to choose) adoption and many healthy infants (mostly white) were placed, often in great secrecy because of the stigma associated with illegitimacy, with unrelated, childless, adoptive parents. The number of nonrelative adoptions increased from about 33,800 in 1951 to 89,200 in 1970. After 1970, the number of children available for adoption, their age and status began to change. The widespread use of birth control, the availability of abortion, and the greater acceptance of single parenthood reduced the availability of infants for adoption by unrelated couples. As a result, the number of unrelated adoptions declined rapidly through the 70s, though it still accounts for nearly half of all adoptions (1). The private adoption of a healthy infant is today an often-expensive undertaking, out of the reach of many middle class couples.

In parallel with the changes affecting the availability of babies for private adoption, two other groups of children became increasingly recognized as suitable for adoptive placements. First, in the mid-1970s, there was a new recognition of the numbers of children living, often in significant instability and for many years, in temporary foster care family placements because of neglect and abuse in their families of origin. In the 1980s, there was a move toward planning for permanency, and an acceptance that children, even older children previously seen as "unadoptable," might benefit from adoptive placement. The Adoption Assistance and Child Welfare Act (1980) was designed to prevent children in foster care from languishing in these temporary situations, and to facilitate adoption for children who could not be reunified with biologic families. Congress passed the Adoption and Safe Families Act (ASFA) in 1997. This legislation requires planning for permanence for children in foster care within a year of removal, and termination of parental rights for children who have been in foster care 15 out of the last 22 months. The Adoption Promotion Act (2003) gave enhanced incentives for adoption of older children. As a result of these shifts in policy and legislation, many children from the foster care system have been placed for adoption, both in unrelated families and with relatives in the so-called "kinship" placements. The statistics on the numbers of children adopted with public child welfare agency involvement are the most reliable and up to date, and rose nationwide from approximately 25,000 in 1995 to around 50,000 in each of the last 5 years (2). For the most part, the focus of policy and professionals working in this area has shifted over the last 100 years or so from a focus on adoption for the psychological or financial benefit of the adults involved toward adoption for the psychological benefit of the child.

The second largest group of children affected by changes in adoption practices has been children adopted from overseas (3,4). These so-called "international" adoptees began arriving in large numbers to the United States and Europe in the aftermath of World War II and the wars in Korea and Vietnam. Many of the first Korean adoptees, who began arriving in 1955, were the offspring of non-Korean military fathers and

Korean mothers; however, international adoption from Korea has continued, though in lesser numbers, ever since. More than 150,000 Korean children have been adopted by US parents. American parents have continued to adopt children from other countries, including China, Russia, India, Romania, Guatemala, Colombia, Haiti, Uganda, and Ethiopia. Chinese children, mostly baby girls, have been adopted by American parents in large numbers over the last 30 years (5). For some years, significant numbers arrived from South American countries, including Guatemala and Columbia (6), and, most recently, larger numbers have arrived from parts of Africa. In the United States and other countries—Sweden, Denmark, and the United Kingdom in particular—this has resulted in a phenomenon known as "visible" adoption: that is, because of the child's and parents' physical appearance, it is obvious that the child is adopted.

Clinicians are likely to encounter the adoption triad of the adopted child, biologic parent(s), and adoptive parent(s), affected by adoption in notably different ways. First, there are children relinquished by their biologic parents, and adopted through private agencies, or independently through attorneys, clergy, or physicians. These account for around 50,000 adoptions a year, a significant decline from the peak of the 1950s and 1960s. Most children adopted by this route are adopted as babies and young infants, either directly from hospital or after short periods in relatively good quality foster homes. Second, the practice of international adoption means that many young children, most between the ages of 3 months and 3 years, arrive in the United States from overseas, after spending time in orphanages, with relatives or in foster homes, where their care may have been less than optimal and about which reliable information may be missing. The adoptive families of many privately adopted US-born and international adoptees are, because of the expense involved, relatively socioeconomically advantaged. Third, about 50,000 children a year are adopted, either by unrelated families who may also have been their foster parents, or by relatives, from the publicly funded child welfare system. More than half of these children are adopted after the age of 6, many of them in adolescence, and they include an over-representation of racial and ethnic minorities. Most have been in foster care for more than 4 years, most often because of significant trauma and neglect. Their adoptive families are somewhat more likely to be older, single parents, and financially less well-off. One notable change in adoption practice over the last 20 years has been the increase in openness in adoption. Openness refers to the degree of contact between the adopted child's families of birth and adoption. The level of contact ranges from the exchange of cards or letters through the placing agency to ongoing personal visits between the two families. Open adoptions have been offered by private agencies since the late 1970s, and increasingly by international adoption agencies. It remains a controversial issue and may be particularly fraught when the adoption follows abuse or neglect in the family of origin. Some authors (7) refer to the adoptive kinship network. This concept sees the child at the center of an extensive

family system that includes birth and adoptive relatives and extended family.

Adoption has, therefore, a long history and has impacted many millions of children and adults. Most estimates are that 2.5% to 3.5% of the current US population is adopted. It is a practice that is likely to continue, driven by the needs of orphaned, abandoned, and neglected children worldwide, and by the profound desire of adults to nurture children of their own. Even though the majority of adoptions result in well-adjusted, well-loved children living in contented families, child and adolescent psychiatrists will continue to see all three components of the adoption triad—birth parents, adoptive parents, and adopted children—in their clinical practices. Attempts to answer some of the questions that arise from the natural experiments of adoption will continue to give rise to fascinating and productive research.

NORMAL DEVELOPMENT IN ADOPTIVE FAMILIES

Most adopted children and families appear to fare well, and follow a normal developmental track. Almost all adoptive professionals and families today support telling children early about their origins and the circumstances of their adoption. The increasing numbers of visible adoptions, adoptions of older children, and the practice of increasing openness in domestic infant adoption (8), has had the beneficial effect of lessening secrecy and stigma. Giving children information early, even before they are ready to wholly comprehend the information, leads to a process of understanding governed by the external facts, the child's internal cognitive and emotional development, and the family's ability to talk comfortably about the issues.

At some point in their development, many adopted children will ask difficult questions about their origins. Their adoptive parents will therefore need to find ways to answer honestly and openly, or help their children come to terms with gaps in knowledge. Just as young children whose parents divorce are likely to see themselves as responsible for the divorce, because of their behavior or attitude, so some adopted preadolescent children may assume that they were given for adoption because they were in some way damaged or defective, or unwanted because they were a boy, not a girl, or vice versa. As in other families referred for clinical intervention, it is not uncommon to find that the children have not shared such feelings or thoughts, sometimes because of a wish to protect their parents' perceived vulnerabilities. Although systematic research has not demonstrated it, it is also not uncommon, or surprising, to find adoptive children anxious about being removed from their adoptive families.

Adolescence appears to be a particularly sensitive time for many adoptive families, and possibly a significant stressor for adopted children, for a number of reasons, some inherent to the normal developmental process of adolescence, and some unique to the adoptive situation. The process of developing and focusing self-

identity is clearly impacted by the reality of adoption. Some adopted adolescents have little information about their biologic roots and families, and some adoptive parents are made uncomfortable by their child's curiosity. The wish of some adopted adolescents and young adults to search for their biologic family, and meet their first parents, often welcomed by those biologic parents, is, sadly, for some adoptive parents exquisitely painful and may be experienced as rejection, even when the adolescent does not have that intent. Greater satisfaction among family members with the contact that does occur appears to predict better adolescent adjustment (9). Sadly, in some families, this issue becomes focused on the idealization of the biologic parent, and used as a weapon in a war of control around the adolescent's emerging independence.

The challenges of normal parenting are focused in somewhat different ways for some adoptive parents, even when the adoption takes place in infancy. Adoptive parents must relate to children who may not resemble them physically or psychologically, may be placed with them abruptly, and with little preparation, or with whom the legal course of adoption may delay the development of confidence in a future with the child. Moreover, many adoptive couples have already faced the considerable and often prolonged trauma and grief of infertility and its treatment. Research and clinical experience support the view that unresolved grief over the loss of the potential for a natural child may interfere with the emotional availability of new adoptive parents. As their children grow, some adoptive parents may face questions and doubts, from themselves, the child and from others, about their role and abilities in comparison to "real" parents. Some extended families may compare an adopted child negatively with "real" children. Even where such overtly pathologic attitudes are not apparent, it has been suggested that some parents experience difficulties in attaching to, owning, and accepting an adopted child (9).

IS ADOPTION PATHOGENIC?

Even before the recent upsurge in the adoption of children from the welfare system, adopted children were overrepresented in clinical populations. Some of the literature supporting this finding dates from a time when most adopted children were placed in their adoptive families as infants, and many in secrecy. Studies from the 1960s, cited by Durdeyn (9) in a previous edition of this text, establish that adopted children were overrepresented in outpatient settings, and tended to be referred for externalizing behaviors.

More recent studies (10–13) support the conclusion that adopted children are more commonly referred and admitted for inpatient psychiatric treatment when compared to nonadopted children, and for less severe problems (11). Some evidence (12) suggests that differences seen between adopted, foster, and nonadopted children in behavioral problems and rates of referral were the result of a small group of

influential cases, rather than a reflection of the group as a whole. Studies of large population samples confirm that being adopted increases the risk for psychiatric illness (14–16). Juffer and van Ijzendoorn (17), in a meta-analysis of a number of studies that included more than 10,000 adoptees, found no differences in self-esteem for international, domestic, same race, and transracial adoptees. However, studies have shown slightly higher rates of externalizing symptoms in adolescence, of self-reported offending and substance abuse (14), higher scores on items reflecting unhappy, anxious behavior, and problems with peer relationships (18), and the suggestion of an increased risk for suicide during adolescence (19). Studies of school and court populations (20) support the finding that problems in psychological and social adjustment are more common in adopted children than in the general population, and are not simply related to increased referral (20). Increased risk for problems does appear to continue into adult life, with recent studies demonstrating increased risk of substance use disorders and personality disorders in adult adoptees (21).

Although these studies demonstrate that adoption for a minority of children appears to be a risk factor for psychopathology, it is only so when adopted children are compared to the general population. When compared to children returned to their families of origin, or to those raised in long-term foster care, adoption is clearly beneficial. For most adopted children, the practice has an overwhelmingly positive outcome, and most adopted children are happy and well adjusted.

The natural experiment of adoption has played an important role in the exploration of the etiology of mental illness, particularly schizophrenia, demonstrating the biologic underpinnings of the disorder (22–25). Studies of adopted children at high risk for schizophrenic illnesses demonstrate that these children exhibit subtle developmental delays, cognitive problems, and poor interpersonal relationships. More recent studies have also examined the contribution of environment, including family environment, to the manifestation of the schizophrenic illness, and support the notion of gene–environment interactions. Using a Finnish sample of children adopted by unrelated parents, Tienari et al. (23) showed that disordered adoptive rearing assessed in the adoptive families predicts schizophrenia-spectrum disorders at 21-year follow-up. The finding was only apparent, however, in adoptees at high genetic risk for schizophrenia, and suggested that adoptees at high genetic risk may be more sensitive to adverse environmental effects in an adoptive rearing environment than were adoptees at low genetic risk. The presumed genotype appears to be "sensitive" not only to dysfunction in the family environment but to protective environmental factors.

Studies like this suggest that adoptive rearing in a quality home environment may be of particular value for those at higher genetic risk. As the possibility that children at high genetic risk for schizophrenia (and other mental illnesses) may be identified in early childhood becomes more realistic, it is possible that adoptive parents, and

the psychiatrists working with them, will have new challenges and possibilities in prevention. They, and we, as their psychiatrists, also face the challenge of counseling the children of such high-risk adoptees as they move into the age of risk for onset of schizophrenic disorders.

INTERNATIONAL ADOPTION

Just as the domestic adoption of children of parents with mental illness has shed new light on the etiology of schizophrenia, so has the international adoption brought new insights into the importance of early childhood experiences (1), even when those are relatively brief, as well as an awareness of the relevance of transracial adoption and immigration in the context of already prejudiced and racist societies.

Studies of children recently adopted from overseas show that growth and developmental delays are frequent, particularly where the child is raised in an orphanage rather than in a foster family setting, or with relatives (6). Three-quarters of the Chinese-born adoptees evaluated in a New England adoption clinic (5) had significant developmental delays, with gross motor delays being the most common. Medical problems were also common, some being minor and easily correctable (anemia, elevated lead levels, hepatitis antibodies, parasites, and positive TB skin tests). Others, though less common, were more serious and included hearing loss, syphilis, orthopedic problems, and congenital anomalies. Many internationally adopted children are also inadequately vaccinated (26). Similar findings (6) come from a cohort of children adopted to the United States from Guatemala, though the problems are not as severe as those in the Chinese children. Adopted children were diagnosed with neurologic problems, including hypo- and hypertonia, clonus, intellectual disability and developmental disorders, and with emotional problems, the latter including depression, posttraumatic stress, and eating disorders. They were also commonly seen to exhibit self-comforting behaviors, such as rocking and banging. This study again demonstrates the significant growth and cognitive advantages experienced by children in foster placements rather than orphanages, prior to adoption. Children who were younger at placement also did better, with those younger than 2 being less likely to be developmentally delayed.

After the resolution of initial medical problems most internationally adopted young children appear to adapt well to their new environment (24), and progress satisfactorily during early school age. A large study in Sweden showed that 92% of the internationally adopted girls, and 82% of the boys (27) had no indication of mental health disorders, or maladjustment. It has, however, been of concern to clinicians in a variety of different countries that internationally adopted children appear more commonly in clinical settings than might be expected. Although not all studies are in agreement, most suggest that a larger minority than would be expected do experience significant mental health problems in childhood, adolescence, and

early adult life. Dutch studies (28–30) show elevated rates of behavioral problems, anxiety, and depression, especially in the home setting, and especially for boys, with adjustment problems increasing into adolescence, even among those adopted as infants. Evidence from the Swedish national registers for those born in 1970–1979, comparing inter country adoptees to the general population found that the adoptees were more than three times more likely to die from suicide, attempt suicide, or be admitted to a psychiatric hospital, and more than five times more likely to use drugs, twice as likely to use alcohol, and somewhat more likely to commit a crime (29–32). Some evidence supports the view that the problems are not that of the whole sample, but rather a result of small group of significant outliers. Cederblad et al.'s (27) study found that preadoption conditions, rather than age at placement, increased the risk of later maladaptation, and that the rate of children with poor attachments increased if the child had been in an orphanage or foster home for a longer time. The problems of the minority of adoptees at risk do persist into adult life, with identified increased risk of anxiety, mood, and substance abuse disorders as adults (33). Cederblad et al. (27) also found that a substantial number of their subjects had been teased or felt ill at ease because of foreign looks, and two-thirds had been regarded as foreigners. Indicators that the young person was struggling with identity were related to level of symptom load and self-esteem, though most subjects coped well with their "special outsider" status. The issue of transracial adoption has been a sensitive and emotive topic, not only as regards international adoption, but as it pertains to the adoption of (mostly) black children by (mostly) white families in the United States. In a comprehensive review of the issue, Rushton and Minnis (34), in a comprehensive review of the data, acknowledge the highly contentious nature of this subject, and its political and social context. Most empirical research has been done on black infants in white adoptive families in the United States, but other transracial placements include Australasian peoples and gypsies in central Europe. Rushton and Minnis conclude that the available evidence suggests that such placements have satisfactory outcomes in over 70% of placements, comparing favorably with other samples.

Overall, studies of internationally adopted children demonstrate that most fare well, and that it is the minority who experience mental health problems. A number of factors may play a part in increasing the risk. Those factors include being male, being placed with a single parent, or in an adoptive white collar family, older age at placement, and placement in an orphanage rather than a foster home prior to adoption. It is also important to remember that adoptive parents may be, to some degree, super-competent, and that children who fare well in adoptive families may be at genetically higher risk than the general population, but environmentally somewhat protected. These studies also bring forth the subtle, and sometimes not so subtle, challenge of growing up with a distinct and different appearance, in a culture that may not welcome difference, or may even be overtly racist and discriminatory.

Many internationally adopted children come to the United States, and other

Western countries, with the assistance of long established international adoption agencies that have worked extensively in the social welfare systems of the countries of origin of the adoptive children, and cooperate with them in providing enhanced orphanage or foster care environments. In contrast, the children adopted into largely middle class American and European families after the fall of the Ceaucescu regime in Romania had experienced extraordinarily deprived orphanage conditions. Their story (35–37) illustrates both the impact of early emotional and social deprivation on child development, as well as the degree of recovery possible in an enhanced family environment. For this group of children, exposed to extreme early global deprivation, duration of emotional deprivation predicted cognitive outcomes at the time of adoption, as well as recovery in the adoptive family. In these studies, the age of "late" adoption was 24 to 42 months—in earlier studies, children placed under the age of 5 are mostly classified as "early" placements; this shift acknowledges the growing understanding in the adoption field of the importance of experiences in the first years of life. Julian's review (37) demonstrates that institutionalization beyond a certain age is associated with lasting difficulties, and that the more severe the deprivation, the earlier the age at which the risk becomes apparent. The Romanian children exposed to longer periods of deprivation were more delayed; those placed at an older age appeared to recover less completely; and, even for those placed at younger ages, the most extensive recovery took place in the first 2 years after placement. Studies of these children as they move into adolescence suggest that a minority, at least, continue to experience particular ongoing problems in social relationships. Some of the behaviors typical of such children when referred for clinical evaluation are described in Stein (38). They include inappropriate social behaviors, attachment problems, odd and bizarre behaviors, language delays, defiance, noncompliance, and anger.

CHILDREN FROM THE WELFARE SYSTEM

For many years, social policy dictated that although babies and young infants could be adopted, children removed from their families by the welfare system or placed by their families after infancy were considered unsuitable for adoption. Social policy shifted significantly, however, in the seventies, as the numbers of children in foster care (and the public expense of their care) grew, and evidence emerged that even older children adopted after adverse care experiences did well after adoption, many better than those who went home to their biologic families (15,16,39,40). It is clear, however, that children adopted older, especially after adverse childcare experiences, have more psychosocial difficulties than those adopted as babies (41,42).

Howe (41) looked at a group of more than 200 adopted children, now young adults, and interviewed their parents. The subjects were baby adoptions, children adopted older who had good care as babies, and children adopted older who had

poor care as babies. The latter group was the only one with higher rates of adolescent problems; however, even among that group, no problem behaviors were reported in more than one-fourth. Behavior problems include peer relationship difficulties and the lower likelihood of having a special friend (42). The findings from more recent studies (43), including those of the Romanian orphans, as well as research on the infancy attachment process, suggest that adoption, in most situations, is a potential massive positive intervention in the lives of maltreated children, and demonstrates the plasticity and resiliency of human neurobiologic systems (45). For infants, the timing of placement for permanency (which in most cases means adoption) is a matter of some urgency and that the infant's development (or maldevelopment) proceeds at a pace that is unlikely to be congruent with the timelines of juvenile courts (44). Although the evaluation of potentially abusive families, and the associated legal processes, can be quite lengthy, it is possible and, from a child developmental point of view clearly advisable, for these processes to continue while the child is given the potential for permanence through the so-called "concurrent planning."

It is unlikely that child and adolescent psychiatrists will have extensive involvement with those children adopted from the welfare system who are doing well. However, many clinicians work with the children and families of those who are doing poorly. As a result, clinicians are likely to see adoptive families struggling with children with extreme behavioral and emotional difficulties, especially in relationships within and outside the family, and, at times, be involved in the heartbreaking situations with adoptive families where the placement is disrupted (family breakdown prior to the finalization of the adoption) or dissolved (family breakdown after the adoption is finalized). Breakdown rates of older adoptions are 10% to 50% (46).

CONCLUSION

Adoption touches many lives. Many adults joyfully become parents through adoption, and would be insulted by the suggestion that this is in any way a lesser means of becoming parents. For a minority of adopted children, the process may contribute to, or be associated with, emotional and behavioral problems, and psychiatric disorders. Children at particular risk include those adopted later in life, after early adverse experiences, as well as those at particular genetic risk. However, for most of the babies and children of all ages who find permanent families through this process, adoption has a positive outcome, contributes to positive psychological adjustment, and is clearly protective. It is also important not to neglect, or ignore, the biologic parents and families of children relinquished or removed and placed for adoption. They too may be our patients. Clinicians working with adopted children and their families should be aware of the complexity and variability of the circumstances in

which adoption takes place, as well as the meaning of the process for all the individuals involved.

CHAPTER 7.4.4 ■ MALPRACTICE AND PROFESSIONAL LIABILITY

PETER ASH AND BARRY NURCOMBE

Malpractice litigation and other forms of formal legal investigation of medical care, such as state medical licensing board investigations, are society's means of holding physicians to appropriate standards and compensating patients who have been negligently harmed. There are problems with utilizing litigation to achieve these goals: it is an inefficient way of compensating patients, since many who have been harmed do not sue (1), many who have suffered damage and do sue were not harmed by negligence, and the costs of litigation, both financially and emotionally, are very high. Physicians who have been sued describe the process as extremely painful emotionally, even when they prevail (2). Practicing defensive medicine is common (3), though probably less of an issue in child psychiatry than in more technologic medical specialties, and some psychiatrists may avoid taking on the most difficult patients. Physicians understandably hate being sued. In the United States, malpractice premiums have increased markedly over the past 30 years, triggering calls for legislative tort reform. Over half the states now have limits on noneconomic damages (pain and suffering) (4). More systematic reforms of the system have been called for, such as moving to a no-fault system adjudicated administratively, along the lines of the worker's compensation system, but such proposals currently have very limited political support.

Compared to many medical specialties, child and adolescent psychiatry is not high risk. Even when sued, child and adolescent psychiatrists prevail most of the time. While accurate national data are difficult to come by because insurance companies keep much of their loss experience as proprietary information, analysis of the psychiatry dataset of the Physician Insurers Association of America from 1985 to 2000 for child and adolescent patients indicated that only about 14% of claims resulted in a payment, and the average payment was less than the average payment in adult psychiatric malpractice cases (5). These positive outcomes are reflected in the practice of some insurers giving discounted premiums to child and adolescent psychiatrists.

Malpractice litigation is not the only arena in which physicians have professional liability: medical licensing boards investigate complaints, as do ethics committees of professional associations. While such investigations do not directly result in monetary damage payments, in medical licensing investigations the ability of the clinician to practice may be at stake, and findings of fault may later be admitted as evidence in a malpractice case.

THE LAW OF MALPRACTICE

THE LAW OF MALPRACTICE

The term *malpractice* refers to an act or omission by a professional in the course of his or her professional duty that causes or aggravates an injury to a patient or client and is the consequence of a failure to exercise a reasonable degree of prudence, diligence, knowledge, or skill. To substantiate malpractice, the plaintiff must establish the following four points, known as the 4 Ds, by a preponderance of the evidence:

1. The clinician had a ***Duty*** *of reasonable care* to the patient
2. There was a ***Dereliction*** *of that duty*, when judged by the standard of the average, prudent practitioner
3. The patient sustained ***Damage***, a compensable injury or harm
4. 4. The damage was a ***Direct*** *result* of the clinician's failure to exercise a reasonable standard of care

Duty of Care: The Doctor–Patient Relationship

The clinician owes a duty of reasonable care toward a patient when a professional relationship exists between them. This relationship is formed when a clinician explicitly or implicitly agrees to provide care to a patient. The clinician thus enters into a contract that binds him or her to provide a reasonable level of care in return for a valuable consideration (the fee). Unless the clinician has unwisely promised a cure, he or she is not bound to provide more than a reasonable level of care.

The doctor–patient relationship cannot be imposed on a competent patient, nor can a doctor be forced to care for a patient except in special situations, such as an emergency room. Controversial situations arise when it is argued that a relationship has been implied by the physician's actions or words. For example, the discussion of a patient's condition by telephone before transfer to a different hospital has been held to imply a contractual relationship (6). Payment is not necessary; even free advice can create a professional relationship. The clinician should be careful about giving casual advice at cocktail parties and the like, lest it be construed that a contractual relationship has been formed.

Conversely, a physician cannot be forced to treat patients who are unable to pay for services or to use a treatment that he or she is not competent to implement. The physician also has a legal (though perhaps not an ethical) right to refuse to give aid in an emergency. Good Samaritan laws have been enacted to protect from liability those physicians who do render emergency aid, unless they have been grossly negligent (e.g., abandoning a live patient who is still hemorrhaging).

When working with minor patients, it is important to be clear with the family who the patient is. In some types of family work, the "family" is defined as the patient, and the clinician may thereby establish a doctor–patient relationship with each member of the family. When the minor is the identified patient, the physician is not taking on

responsibility for treating the parents, and communications from the parent about the child are placed in the child patient's record. However, when advice is given to a parent in a separate parent session (e.g., "Your child would be better off if the two of you divorced"), the physician is likely to be held responsible for the foreseeable consequences of that advice.

The Internet allows doctors to communicate with patients in new ways. Email communications between a patient who is or will be seen in the office clearly fall within an established doctor–patient relationship. Responding to a nonpatient's email with therapeutic advice may establish a doctor–patient relationship, much as if a similar communication was conducted over the telephone (7). Simply responding to a prospective patient's email with a referral to someone in their geographic area does not establish a doctor–patient relationship. While the law is still evolving in this area, the trend is that the medicine is practiced in the state where the patient resides, not where the physician practices (8), so physicians who conduct email treatment with a patient who resides in a state where the clinician does not have a license may be practicing without a license. Prudent risk management dictates that professional email communications with nonpatients that might be construed as therapeutic contain a clear disclaimer that the email does not constitute professional advice and refer the patient to their physician for such advice. Similarly, general information about mental health conditions which a physician may post on his or her website should likewise contain a disclaimer. Professional risk management organizations have developed guidelines for practitioner websites and email practices (9,10).

As psychiatric practice has become more focused on psychopharmacology, collaborative treatment relationships have become more common. The most frequent relationship is one in which the psychiatrist handles medications while another mental health professional conducts psychotherapy. As team medicine and medical homes become more common, another type involves the psychiatrist intermittently seeing the patient but another professional, such as a pediatrician or nurse practitioner, does the bulk of the prescribing. These relationships often leave ambiguous which clinician is responsible for what and how responsibility for care is to be shared. In the event of an adverse outcome, the question of who is potentially liable arises. It is important that the psychiatrist and other professionals are clear on their responsibilities, including what the physician's role will be, who is providing emergency coverage, and the expectations of communication between the collaborating providers. This understanding should be shared with the patient, and the discussion documented.

After the termination of the contract, the physician owes no further obligation to the patient other than that of confidentiality. Physicians who terminate contracts unilaterally and without reasonable cause are at risk of actions for *abandonment*. The physician must give the patient due notice of termination and must ensure that necessary arrangements are made for alternative care. If the patient resists

termination, failure to refer to another physician may be construed as negligence. Some risk managers advise that patients be notified at the outset that noncompliance with treatment is deemed a termination of treatment.

Vicarious Liability

In accordance with the doctrine of *respondeat superior* (let the master answer), a physician is legally responsible for the negligent actions of employees or supervisees. Thus, a psychiatrist may be held liable for the negligent or outrageous actions of his secretary and office staff or house officers whom he or she supervises. In malpractice cases involving inpatients, the hospital is often a defendant because of its vicarious liability for the actions of nurses, ward staff, and house officers.

Supervising and Consulting Relationships

Supervisors who provide care, supervise the care of residents, or are the attending physician of record face malpractice exposure for the care they direct, and may be held liable for care they supervise, either as vicariously liable for the actions of a house officer, or as directly liable for inadequate supervision. Consider a suit filed subsequent to an adolescent's suicide after the adolescent was brought to an emergency room and examined by a resident who discharged the patient after discussion with the chief resident but without telephoning the attending child psychiatrist. Assuming the overall care was found negligent, courts may apportion blame differently, depending on local interpretations of whether residents are held to the standard of specialists and the nature of the contract of the on-call attending (who has been found vicariously liable in some cases even when not contacted). If the attending had been called, then the apportioning problem is still complex. At this time there exists no clear standard as to what constitutes reasonable supervision (11,12).

When the physician is asked by another clinician to see a patient, the consulting physician's liability for malpractice is governed by whether a doctor–patient relationship was created. If the consulting physician provides consultation to the treating doctor, but does not write orders or otherwise direct the treatment, then ordinarily no doctor–patient relationship is formed, and the consultant's duty is only to the consultee doctor. However, if the consulting physician writes orders or otherwise directs care, then the court will usually find that a doctor–patient relationship was created.

Clinicians may examine people on behalf of a third party, such as a school or insurer, to whom they owe a contractual duty. However, if the examination causes the examinee harm, for example, by failure to detect suicidality or the possibility of child abuse, the liability risk is ambiguous. Some courts have held that the clinician's duty is to the employer; others have held that, if the person being examined reasonably

relied on the examination for diagnosis, a duty may be owed. The physician is advised to inform the examinee that the purpose of the examination is not therapeutic. In court-ordered evaluations, courts typically find that the evaluator is immune as an agent of the court (13).

Fiduciary Relationship

The clinician's obligations toward the patient go beyond the duty to provide reasonable care. The relationship between the psychiatrist and patient is analogous to that between the guardian and ward. The patient has a right to expect the physician to show good faith, that is, to act in the patient's best interest. This, the physician's *fiduciary duty,* is especially onerous in psychiatry, because emotionally disturbed people share their most private experiences with their mental health clinicians and are thus very vulnerable. Improper sexual contact, invasion of privacy, breach of confidentiality, outrageous manipulation of the patient's emotions, and the exploitation of patients for financial gain are all examples of *double agentry* and *breaches of fiduciary trust.* These *intentional torts* are discussed later in this chapter.

Dereliction of Duty: Breach of the Standard of Care

In accordance with the contract inherent in the doctor–patient relationship, the physician is bound to provide a reasonable level of care. In other words, the physician contracts to provide reasonable, prudent, diligent, knowledgeable, and skillful medical care. Unless the clinician has unwisely promised a cure, the contract does not call for exceptional care, only a level of expertise equivalent to that exercised under similar circumstances by the average practitioner in the same field of medicine. *The clinician is not liable for an error of judgment unless the error represented a substandard level of care.* If the clinician exercised reasonable judgment, the clinician is not responsible simply because the patient suffers a bad outcome. If clinicians differ as to how a particular issue should be addressed, it is enough to show that there is a respectable minority who endorse the approach that was taken. The considerable variation among clinicians in methods of treatment has made standards difficult to establish, particularly in regard to psychotherapy where there are many different approaches. The standard is tighter with regard to precautions against suicide or violence or the monitoring of medication.

The standard of care traditionally required that the clinician be judged by the professional standard in the locality. However, the emergence of national standards has caused the courts to move in this direction, with allowance for the paucity of resources in some areas. Since the statute of limitations typically does not begin to toll until a child reaches the age of majority, cases involving children may be filed

many years after the alleged malpractice took place. The standard of care is linked to the standard of professional practice at the time of the alleged breach of duty. If a clinician practices medicine in a specialty area for which he or she is not trained, the clinician is likely to be held to the standard applying to that specialty.

Breach of the Duty of Care

Malpractice suits are founded in the legal theories of intentional and negligent torts. A n *intentional tort* involves deliberate intent on the part of the wrongdoer or wrongful conduct that the wrongdoer ought to have known was unacceptable (in which case it is known as a *quasi-intentional tort*). Examples of intentional torts are assault, battery, false imprisonment, fraudulent commitment, defamation, invasion of privacy, sexual exploitation, and the intentional infliction of emotional distress. Expert testimony is not required to substantiate an intentional tort, and malpractice insurance may not cover it. A *negligent tort* involves an unintentional error that reflects a failure by the clinician to exercise a reasonable standard of medical care. Expert testimony is required for proof of negligence.

In determining whether treatment fell below the standard of care, the courts may look to a variety of sources, and inquire whether the treatment:

1. Violates a statute (such as the child abuse reporting law or HIPAA regulations)
2. Violates a licensing board regulation or other regulatory agency holdings (such as FDA guidelines)
3. Violates an ethical principle of the profession (such as confidentiality)
4. Violates case law (such as the *Tarasoff* duty to protect)
5. Violates the professional consensus of the community

Professional consensus is the least clear of these elements, and the one about which expert opinion at trial most often differs. When there is no disagreement about what treatment the defendant doctor actually provided, the difficult question is whether that course was reasonable in the specific case at issue. When professional organizations began developing published practice parameters or practice guidelines, clinicians were concerned that such guidelines would create liability by setting the standard of practice. In response to this concern, published guidelines typically contain disclaimers stating the guidelines do not define a standard of practice. Courts frequently allow experts to discuss professional guidelines in their testimony as indicators of standard practice, but acknowledge that they do no set a standard of practice and that approaches may deviate from general guidelines in individual cases (14). Guidelines have often proved useful to defendant doctors by indicating that a range of approaches are acceptable. In day-to-day work, in considering a course of action, a clinician should ask himself, “What would my peers think of this?” and “What would I think if a colleague told me he was going to do this?” If the answer is that the colleague would be concerned, then the physician should consider the

approach carefully and document the rationale fully.

Damage, Harm, or Injury

Harm may be physical or psychological. Physical harm or damage resulting from negligence includes, for example, side effects of medication such as tardive dyskinesia, physical injury incurred when a patient is improperly restrained, or homicide or suicide. Psychological damages may be of two types: general pain and suffering, and damages to the patient's mental health. Expert testimony is not needed to establish pain and suffering: the jury can draw its own conclusion as to how much suffering it thinks a normal person would suffer given a particular harm. Psychiatric evidence may be utilized to inform the jury about the impact of an injury on the plaintiff's capacity to enjoy life. Mental health damages typically require expert testimony, as, for example, when a plaintiff alleges that her major depressive disorder has been aggravated by traumatic treatment. Injury to a parent or child may give rise to an action for loss of consortium, that is, loss of the care, comfort, and society of a spouse, parent, or child.

Proximate Cause

The plaintiff must substantiate that the defendant's wrongful act or omission directly caused or aggravated the patient's injury. In other words, it must be proven that, but for the wrongful conduct, the damage would not have occurred, or would not have been aggravated, or that a direct, uninterrupted link or foreseeable chain of events exists between the wrongful conduct and the injury or its aggravation. The legal concept of *cause* is analogous to the psychiatric concept of *precipitation* or *aggravation.*

Some states have comparative or contributory negligence rules that instruct juries to consider whether the plaintiff's negligence, such as failing to inform the clinician of a worsening condition, or failing to cooperate with treatment, contributed to the bad outcome, and reduce damages accordingly. Because a child or adolescent patient's responsibility is generally held to be lower than that of an adult, comparative negligence issues are uncommon in child or adolescent malpractice cases.

Restitutive Payment

If the defendant is found liable, the judge or jury may award damages. Damages are designed to be *compensatory,* that is, to recompense the victim for medical expenses, pain, suffering, loss of enjoyment of life, impairment of capacity, and future loss of earnings and to restore the plaintiff to his or her original position, so far as money is

able to do so. If the defendant's behavior has been egregiously outrageous, malicious, or wanton, *punitive* damages may be imposed over and above compensatory damages, but are rare in malpractice cases. By federal law, all payments whether as a result of settlement talks or by trial verdict, are reported to the National Practitioner Data Bank (15).

Managed Care

Although managed care has had considerable impact on clinical practice, it has had rather little impact on malpractice litigation. From the law's perspective, the clinician is responsible for prescribing needed treatment and managed care deals only with payment of fees. In *Wickline v. State of California* (1986) (16), the court affirmed the physician's duty to prescribe care, and suggested that the physician had a duty to appeal adverse decisions made by managed care reviewers. In clinical practice, clinicians routinely take into account the ability of the patient to pay in making treatment recommendations.

A number of states have attempted to pass laws holding managed care entities liable for denying authorization or payment for needed care. However, most managed care contracts are employee benefits, and are covered under the federal Employee Retirement Income Responsibility Act (ERISA). Congress originally passed ERISA to regulate pensions, but it has been interpreted to cover employee health care benefits as well. ERISA has two major prongs that limit the liability of managed care companies: first, it preempts any state law with which it conflicts, and second, it limits the damage for error to the amount of the benefit denied (the cost of treatment). Thus, state laws which assign liability to managed care are voided, and the most the patient can recover for improperly denied care is the cost of the care. The courts have recognized that this leaves patients with little redress (17), but reform, the so-called "patient rights" legislation, requires congressional action.

In malpractice litigation, managed care issues rarely surface: physicians are reluctant to argue that their care, which resulted in a bad outcome, was limited by financial considerations, and plaintiffs are reluctant to assert that they happily would have paid for expensive care out of pocket if only the doctor had recommended it.

COURSE OF A TYPICAL CASE

If a clinician's patient suffers a serious adverse treatment-related event, the clinician should report the matter to his or her insurer and follow their risk management advice. With minor patients, the parents control access to information, so no formal release is necessary to discuss with them what occurred, unlike in cases involving adults. A number of states have passed legislation which prohibits apologies or expressions of sympathy or regret from later being admitted as evidence of physician

negligence. Peer-review activities, such as morbidity and mortality conferences, are not discoverable to prove liability in most states. The clinician then enters an uneasy waiting period to see if suit is filed. For minor patients, the statute of limitations (the period during which suit can be filed) typically does not begin to run until the child becomes an adult, so the wait can be quite long. Attorneys for plaintiffs in malpractice actions typically work on a contingency fee basis in which they initially bear the costs of litigation. Attorneys therefore screen cases carefully before making a judgment that spending the time and money to pursue the case is likely to be profitable. In most states, in order to file a malpractice claim, the plaintiff's attorney needs to obtain an affidavit from an expert asserting that the care rendered was below the standard of care. If the physician is served with notice of being sued, the malpractice insurance carrier should immediately be notified.

After suit is filed, the discovery phase begins, which will involve both sides retaining experts and taking depositions, including the deposition of the defendant doctor. Settlement talks also occur in this period. Whether the malpractice insurer can settle without the agreement of the defendant doctor depends on the terms of the insurance contract. If the case does not settle, it progresses to trial. Halleck (18), an experienced forensic psychiatrist who had himself testified in numerous malpractice actions, has described how emotionally wrenching even he found being a defendant. If money is paid to the plaintiff, either as a product of settlement negotiations or a court verdict, the amount and doctor's name are reported to the National Practitioner Data Bank, and the information is available to credentialing bodies, licensing boards, insurers, and managed care entities. This publicity has reduced doctors' willingness to settle a case for "nuisance value."

CIRCUMSTANCES IN WHICH MALPRACTICE IS MOST LIKELY TO OCCUR

While in many ways child and adolescent malpractice cases are similar to adult malpractice cases, only involving younger patients, they differ from adult cases in a number of respects. First, minors are less responsible for their acts, which tends to shift responsibility to the clinician and the parents. Second, minors typically cannot consent to treatment, which introduces a third party decision maker, usually the parents, into the case. Third, parents are often involved as quasi-patients because they receive advice from the clinician. And finally, juries are sympathetic to injured children. While an allegation of malpractice can involve any aspect of practice, the vast majority of cases fall into one of the several areas shown in Table 7.4.4.1.

TABLE 7.4.4.1

COMMON ISSUES IN MALPRACTICE LITIGATION

Area of Practice	Example Plaintiff Allegation
Dangerousness	
Suicide	Weak suicide assessment documentation: "SI–"
Homicide	No violence risk assessment in chart
Failure to protect from danger	Inpatient sexually assaulted by another inpatient
Failure to protect third parties	Dangerous patient escapes from hospital and family not notified
Protecting and releasing information	Confidential information released without authorization
Treatment	
Failure to obtain informed consent	Possible side effects not discussed
Psychotherapy	Implanted memories of sexual abuse
Sex with patient	Therapist had sex with patient
Medication	Girl with bipolar disorder treated with sodium divalproex for 8 mos gives birth to baby with birth defects and there is no documentation of pregnancy status when medication is started
Ending treatment	
Negligent discharge	Patient discharged while still suicidal
Abandonment	Therapist terminated treatment without referral when patient ailed to pay bill

Issues Pertaining to Dangerousness

From a malpractice perspective, the central questions are first, whether the danger was reasonably foreseeable, and second, if it was, whether the clinician took adequate steps to protect the patient and potential victims. Foreseeability focuses on the adequacy of the assessment of risk, and protection focuses on the interventions employed once significant risk is found. While there is general acceptance that psychiatrists lack the ability to accurately predict violence, there is increasing agreement on the standards for assessing the risk of violence.

Suicide

Suicide of a young person is a tragedy. Assessment and treatment of suicidal children and adolescents are covered in detail in Chapter 5.4.3. Assessment of suicidal intent is more difficult in adolescents than it is in adults because the rate of suicidal ideation is so high in middle to late adolescents. The 2013 Youth Risk Behavior Surveillance study found that 17% of high school students had seriously considered suicide in the previous 12 months, 13.6% had made a plan, 8% had attempted

suicide, and 2.7% had made an attempt that required medical attention (19). When these rates are compared to the completed suicide rate of approximately 0.007%, it is clear that the ratio of suicidal ideation to completed suicide is very high (over 2,000:1). Assuming that an adequate assessment was conducted, documentation of the assessment is key. The oft-seen suicide assessment note of "SI–" (suicidal ideation negative) does not offer much protection to a defendant psychiatrist because it fails to document the components of the suicide assessment, such as what history was obtained about prior attempts, family history, plan, etc. Where some suicide risk is present, assessment entails weighing risk factors and protective factors. Good documentation of risk and protective factors, and of the physician's reasoning about intervention, is the best protection in the event of an adverse outcome. On an inpatient unit, the psychiatrist should also document his or her review of the assessments of others, such as nurses and house officers. Timely, clear, legible, pertinent, thorough, dated, timed, and signed records are the key to communication and the best proof that the hospital and staff have exercised reasonable care. In *Abille v. United States* (20), after a psychiatrist transferred a patient from a suicidal status to a less dangerous status, the patient committed suicide. The finding of negligence against the defendant hinged on the psychiatrist's failure to keep detailed records that explained his decision to transfer the patient, even though it was conceded that, under the circumstances, the decision may have been reasonable. Finally, it is important to keep in mind that suicide assessment is a process, and for depressed or suicidal youth, repeated assessments need to be documented.

If a physician determines that the patient is at significant risk for suicide, then he or she has a duty to institute reasonable precautions. If the clinician decides not to hospitalize the patient, it is important to document the protective factors and interventions that were employed. For youthful patients, this often involves utilizing the family to monitor the patient's condition, provide some protection, and alert the clinician if the situation deteriorates. The child or adolescent's risk for suicide should be discussed with the parents. If the patient is in the hospital, it is important to document the physician's review of observations of other care providers and to document the reasons when levels of supervision are reduced.

What if the patient refuses to cooperate with the admitting psychiatrist, who consequently does not elicit and diagnose an imminent suicide risk? In *Skar v. City of Lincoln, Nebraska* (21), a recalcitrant patient injured himself in a suicide attempt. The court found for the defendant and held that the patient had a duty to cooperate with his physician as far as he was able. However, it is essential in such a case that the psychiatrist record the questions put to the patient and the patient's responses or failure to respond. Also, with minor patients who cannot legally consent to treatment, courts are likely to apportion less responsibility to the patient.

Failure to Protect or Control a Violent or Sexually Aggressive Patient

Clinicians and hospitals assume a duty of care toward patients with a potential for violence. The psychiatrist must carefully assess the potential for danger and must ensure that the hospital staff take adequate precautions to protect a violent patient from harming others. Past medical records should be scrutinized concerning violence potential, and referring agents and parents should be questioned. In accordance with the imminence of the risk, housing in a secure unit, confinement to a room, close observation, a search of clothing and personal effects, and removal of all dangerous objects (belts, mirrors), may be required. If the patient is medicated, staff members should check that medication is actually swallowed. It is essential that the degree and nature of risk be communicated to all staff who care for the patient.

The prevalence of sexual abuse and its relationship to psychiatric disorder mean that many minors admitted to psychiatric hospitals are at risk of precocious sexual activity and unwanted pregnancy. Suicide and sexual activity involving latency-aged inpatients have been reported to be the most common types of malpractice action brought against child psychiatry training programs (22). These cases may involve two patients cared for by different doctors, and raise complicated confidentiality problems (e.g., can the plaintiff-victim get access to the medical file of the perpetrator?). The central issues are the foresight involving the risk of the activity occurring, and the adequacy of nursing monitoring of patient interaction. Known perpetrators should be closely observed and housed in single rooms, if necessary. However, the closeness of the possible observation decreases if the therapeutic environment is less restrictive, for example, in a residential treatment center.

Negligent Release or Discharge of a Suicidal or Violent Patient

A patient may harm himself or herself or others while on pass in the grounds of the hospital, on leave with relatives or friends, after discharge, or after absconding from hospital. Was the tragedy foreseeable by a reasonably prudent psychiatrist? This is the question that the courts seek to answer. In doing so, they are aware that the safety of the public must be balanced against the need to rehabilitate patients, that reasonable, calculated risks must often be taken, and that *bona fide* errors of clinical judgment are unavoidable (23).

Increasing pressure by managed-care organizations, Medicaid agencies, and insurers has raised the specter of premature discharge against medical advice forced by withdrawal of funding. The clinician should be aware that legal responsibility for any harm that consequently befalls the patient or community will be placed on his or her shoulders. The risk may be so great that the hospital should bear the cost of continued hospitalization.

Wrongful Injury, Assault, and Battery

A patient injured by staff members who use excessive force to subdue him or her may

have a claim against the hospital for battery or wrongful injury. Wrongful injury may also be claimed when one patient is harmed by another whom the staff could not control; however, the plaintiff would have to establish that the hospital was derelict in its duty to control the violent patient.

Seclusion and restraint present serious liability risks. They may be legitimate management techniques when the risk of harm is imminent and there are no alternatives; but they should not be used to compensate for understaffing. Physical control should be time limited, and the patient should be examined by a physician if the maximum permissible time (e.g., 1 hour) requires extension. Seclusion and restraint should never be ordered "as needed." Quality assurance tracking is required to ensure that the use of physical controls does not become excessive.

If the person causing the harm is a hospital employee, the hospital may be liable, particularly if it were known that the employee had a propensity for violence or sexual misbehavior (24). The hospital may also be liable for the misbehavior of physicians, agency nurses, or others who work in hospital but who are not employed by it. State institutions may claim *sovereign immunity,* which precludes litigants from suing governmental institutions; however, most jurisdictions have greatly limited or abolished this doctrine.

Failure to Protect Endangered Third Parties

Prior to the first *Tarasoff* decision (25) in 1974, clinicians had duties to their patients, but not to third parties. So, if a patient harmed a third party, the patient might have grounds to sue the clinician for failing to treat or restrain him, but the victim could not successfully sue the clinician. This was in line with general negligence principles which hold that in most situations, one does not have a duty to protect third parties. Thus, if a man sees someone drowning in a river, he has no legal duty to help (although he may have a moral duty). In the clinical situation, it was also thought that the patient's confidentiality prevented notifying a potential victim of threats, and that psychiatrists' inability to accurately predict violence limited their ability to intervene.

The first time the California Supreme Court heard the *Tarasoff* case, it found that clinicians did have a duty to potential victims, and that duty overrode the need for confidentiality, holding "The protective privilege ends where the public peril begins" (*Tarasoff I* at 561). The Court also decided that the duty could be discharged by warning the potential victim, which became known as the "duty to warn."

Concerned by the serious implications for patient confidentiality of this judgment, the American Psychiatric Association pressed the appellate court to reopen the case. In an unusual move, the Court did so, and in *Tarasoff II* (26), the issue of failure to warn was debated. The court decided that there was a *duty to protect* rather than a duty to warn: *if there is a serious danger of violence, the clinician must take reasonable care to protect the foreseeable victim.* The court failed to define what

constituted “reasonable care” and how dangerous the patient must be before precautions should be taken.

Following *Tarasoff,* courts and legislatures in other jurisdictions have wrestled with these issues. The key dimensions that need to be decided are:

1. Is there a duty to protect?
2. If there is a duty, who needs to be protected? Only identifiable victims? The general public?
3. What triggers the duty? Is a specific threat required, or only a clinical judgment of risk?
4. How can the duty be discharged? A warning? Calling the police?

Jurisdictions have answered these questions differently, with about half the states finding a duty, a minority holding there is no duty, and some leaving the question unresolved (27). The trend has been toward legislation specifying what the duty is and how clinicians can fulfill it to avoid liability. Clearly, clinicians need to be aware of the law in their own jurisdiction.

Despite the attention paid to *Tarasoff* issues, clinical cases involving a need to breach confidentiality are uncommon with adolescent patients. In the vast majority of cases in which an adolescent is judged an imminent risk to others, the adolescent is hospitalized and kept in the hospital until he or she no longer poses serious risk. Further, in working clinically with dangerous minors, parents control consent to release information, and they will often consent to involving potential victims (as in family treatment), so problems of breaching confidentiality without consent may often be sidestepped. *Tarasoff* situations most commonly arise in two situations: first, when the patient is not available for intervention, as when a therapist hears about a threat over the telephone or the patient escapes from the hospital, and second, in situations of contingent threats (“I think I’ll pass, but if that teacher gives me an ‘F’, I’ll shoot her”).

What, then, should a clinician do if a patient threatens violence and the situation cannot be managed clinically? First, undertake and document a violence risk–resource analysis. If the risk is serious, take precautions to protect endangered parties, and with minors, discuss the situation with the parents. Second, if the patient is already hospitalized, take precautions against elopement, consider limiting visitation and leave, and do not discharge the patient unless you are convinced that the risk of violence has diminished. Obtain consultation if you are in doubt. Third, if a potentially violent hospitalized patient elopes or fails to return from leave, seek consultation from a colleague and from the hospital’s attorney and inform the parents. If the risk of harm is significant, inform the local police and the police department of the area where the patient lives, by telephone and certified letter. If certain people (family, friends, or acquaintances) could be in danger, warn them by telephone, through the police, and by certified letter. Fourth, if you warn a third party by telephone or letter, take care to divulge only as much as necessary to let them know

they are at risk. Fifth, involve the patient in the warning process. The patient may agree to having a warning given. If you have control of the patient (i.e., the patient is in the hospital or can be kept in your office), let the patient be present when you telephone the police and the third party, allow him or her to read the contents of the letters sent to the endangered third party and the police, and encourage the patient to discuss his or her reactions to these interventions. Knowing the potential victim has been warned may bolster the patient's own self-control.

If the situation is unclear in the home state, the clinician would be well advised to act as though the broadest interpretation of the doctrine applies. However, as Simon (28) points out, one should not allow concern about *Tarasoff* liability to interfere with sound clinical practice. Instead, the clinician should make reasonable efforts to control potentially violent patients before breaching confidentiality; and if warnings are required, they should be incorporated into treatment whenever possible.

Failure to Report Child Abuse or Neglect

All states have mandatory reporting laws requiring mental health clinicians to report a reasonable suspicion of child abuse or neglect, and failure to do so is malpractice. The statutes immunize a clinician making a good faith report, so a report to protective services that is later deemed unfounded is not a basis for malpractice. However, other interventions taken by the clinician based on a conclusion of abuse may be actionable. In *Montoya v. Bebensee* (29), a clinician advised a mother to withhold visitation from a father who was suspected of abuse. The father sued, and the court held that the report to protective services was immune from suit, even if made negligently, but the advice to the mother fell outside the reporting statute and could be grounds for suit, a holding Guyer (30) characterized as "you can sound an alarm, but you can't form a posse." Litigation over recovered memories has addressed similar issues, and is discussed further below.

Protecting and Releasing Information

The Hippocratic Oath includes a precept regarding confidentiality: "What I may see or hear in the course of the treatment or even outside of the treatment in regard to the life of men, which on no account one must spread abroad, I will keep to myself, holding such things shameful to be spoken about." Confidentiality has always been seen as especially central in psychiatry. The issue is complex in child and adolescent psychiatry because the clinician needs to weigh the child's need for privacy against the parents' right to know by virtue of their legally controlling the release of information until the minor patient becomes an adult. In many jurisdictions, the extent to which an adolescent can enforce a privacy right against the parents' control of the record is legally murky. It is clear that parents have a right to know if the adolescent

is involved in a dangerous clinical situation. Many states have allowed minors some control over the record, generally in parallel to the degree that minors in that jurisdiction can consent to treatment. Aside from the legal precedents, children and adolescents value confidentiality in psychotherapy as necessary for feeling comfortable to share sensitive material. While clinicians are advised to be aware of the rules in their jurisdiction, from a clinical perspective, it is important at the outset of treatment to discuss with patients and their parents what information will be shared with parents and under what conditions.

Confidentiality and Privilege

Confidentiality is a duty of the clinician toward the patient that precludes the clinician from divulging private matters revealed by the patient in the context of the doctor–patient relationship. *Privilege* is the patient's legal right to bar the physician from disclosing confidential matters in a court of law. Testimonial privilege derives from statutes in some states, and from court holdings in other states. In *Jaffee v. Redmond* (31) the U.S. Supreme Court held that there was a mental health privilege in federal court. Physicians should consult their local statutes to understand the extent of this privilege and its exceptions. Confusion may occur when a clinician receives a subpoena to appear in court (with or without records). A subpoena merely requires the clinician to appear in court. It does not compel him or her to testify about confidential matters unless the patient has specifically authorized the clinician to do so, or has waived privilege, or unless the clinician is ordered to do so by the judge. Although states vary somewhat in the exceptions allowed to the rule of privilege, the following are the most usual:

1. *Waiver by patient*. The clinician should seek specific written authorization from the patient (or those who legally speak for the patient, such as parents) before disclosing confidential material in court or to other parties.
2. *Evaluation for a reason other than psychiatric treatment*. For example, the psychiatric evaluation of a disputant in a child custody case is not privileged if the evaluation was conducted as part of the case. A similar exclusion applies to evaluations for the purpose of civil commitment.
3. *The patient-litigant exception*. If a patient offers his or her mental health as evidence in litigation, in most states—but not all—he or she generally waives privilege concerning the specific issue in evidence. Similarly, if the patient pleads insanity as a criminal defense, the psychiatric examination conducted to evaluate that matter is not privileged (32).
4. *Duty to protect endangered third parties*. The *Tarasoff* exclusion discussed above applies when the community is endangered.
5. Other limited exceptions authorized by law, such as mandatory reporting of child abuse and civil commitment proceedings.

HIPAA

The Health Insurance Portability and Accountability Act of 1996 (HIPAA) authorized the U.S. Department of Health and Human Services to establish regulations regarding the privacy of medical records, which they did in what is known as the Privacy Rule (33) which went into effect in 2003. The Privacy Rule establishes a federal floor for the protection of protected health information (PHI). In a particular situation, if state law provides for a higher level of privacy protection, then state law controls. For example, some states have statutes that restrict release of mental health records in situations that HIPAA would otherwise allow. The Privacy Rule is complex, and a complete summary will not be attempted here. The Office for Civil Rights in the Department of Health and Human Services provides considerable information on its website regarding the details of the Privacy Rule (34), and many professional organizations provide information and recommendations to their members. Violations of HIPAA and the Privacy Rule can be investigated and prosecuted.

HIPAA has implications for psychiatric practice. First, clinicians covered by the Privacy Rule are required to give patients (or parents) a *Notice of Privacy Practices* at the patient's first appointment. The notice must spell out how clinicians assure privacy and under what conditions and to whom protected health information can be released without obtaining consent. Second, HIPAA gives adult patients the right to see their records (or generally parents, in the case of treatment of children and adolescents), with very limited exceptions. Third, the Privacy Rule restricts third party payer requests for information to the "minimum necessary" information. Previously, insurance companies, relying on the patient's release signed as a condition of obtaining coverage, could, and often did, ask for a copy of the entire chart. The American Psychiatric Association (35) has taken a formal position on what constitutes the minimum necessary information necessary for payment which includes identifying information, diagnosis, treatment plan, and dates of treatment, but excludes much of the detailed material often found in progress notes. Fourth, the Privacy Rule creates a new category of medical record which it terms "psychotherapy notes." Psychotherapy notes, as defined in the Privacy Rule, are notes that are part of the medical record, and so are different from process notes, which the clinician typically holds apart from the medical record and can destroy whenever he or she wishes (except to avoid a subpoena!). However, psychotherapy notes are kept separately from the regular medical record, and can only be released with the consent of the patient, giving such notes substantially greater protection than the regular medical record. Clinicians are permitted, but not required to maintain psychotherapy notes. Psychotherapy notes are the only special category of notes in the Privacy Rule: advocates for AIDS patients and substance abuse patients were unsuccessful in getting special protection for their records. Keeping a second set of records is somewhat cumbersome, and many clinicians do not keep psychotherapy

notes, but rather choose not to document highly sensitive fantasy material.

Emailing and Texting Patients

HIPAA has drawn attention to the electronic transmission of information, of which one common form is emailing patients and texting patients. HIPAA requires that electronic transmission of protected health information be encrypted, although many clinicians ignore this when emailing and texting. Even for those who are not "covered providers" under HIPAA, courts increasingly see HIPAA protections as setting a standard of practice. The potential problems with email are that it can be intercepted and may inadvertently be delivered to the wrong person. For emails that involve sensitive information, it is best to use web-based email that is encrypted. For email that simply has to do with arranging appointment times, encryption is probably not necessary. Texting is generally not encrypted unless both clinician and patients use special applications. Emails can be printed and kept in the record; it is more cumbersome to print text messages.

Emailing or texting for administrative matters, such as appointment scheduling, is probably not a liability problem. If a clinician uses email for substantive discussions about treatment, he or she is well advised to have a written policy about emailing that includes how email is to be used and the limits of confidentiality, and includes a consent form signed by the patient. The American Medical Association (9) and some malpractice insurance companies have developed guidelines for professional use of email. Using texting for treatment issues is more problematic, both because of security issues (cell phones can be easily lost or stolen) and because of the difficulty in keeping a record. Novel smartphone applications that involve communicating with a clinician, such as real-time reporting of mood states or other symptoms, will continue to pose novel challenges. Technologic developments in communication are likely to enter clinical practice faster than standards and regulation will keep pace with them. The basic principles in using these new technologies is to assure that confidentiality is preserved, the patient gives informed consent, and the ability to communicate at any time does not create boundary problems for the clinician.

Telepsychiatry

Telemedicine has become an increasingly common method of administering care, especially given the difficulty in many rural areas of locating a child and adolescent psychiatrist. The vast majority of states require that the clinician have a professional license in the state where the *patient,* not the clinician, resides (36). Some states issue special licenses to allow out-of-state clinicians to practice telemedicine. Most states make exceptions for out-of-state consultative examinations done at the request of an in-state clinician, or telemedicine with an established patient who is temporarily out-of-state. Clinicians need to be aware of the licensing laws in effect at

their patients' locations.

The standard of care is generally considered to be the same as for in-person care. For example, if the patient is in crisis, the clinician needs to know how to handle the problem at a distance. Professional associations have developed guidelines to assist mental health professionals conduct telepsychiatry competently (37).

Improper Release of Information from Medical Records

The unauthorized disclosure of confidential information from a patient's record could be actionable on the ground of breach of confidentiality and also may constitute a HIPAA violation. Medical records should be kept in a locked place in the ward or medical records department to bar access to unauthorized people. The patient or legal guardian must give consent for the transfer of information to agencies such as attorneys, schools, social welfare departments, and insurance companies. It is generally best to obtain written consent, although if this is impractical, witnessed verbal consent is typically acceptable. State laws vary as to whether information relevant to continuing care can be released to other clinicians or hospitals without consent, but it is generally prudent to attempt to obtain consent even in situations where it is not formally required.

If a subpoena is served unaccompanied by a release from the patient or guardian, the clinician has three alternatives: to seek the patient's consent; to have a motion filed by an attorney to quash the subpoena; or to refuse to testify unless ordered by the judge to do so. If the clinician persists in refusing to testify despite the judge's instruction to do so, he or she may be held in contempt of court (38).

Defamation

Defamation involves communication by one party about a second party to a third party that damages the reputation of the second party. Defamation is most likely to occur in child psychiatry when carelessly written medical records are released to third parties. For example, the patient may have been described in the record as a "psychopath" or "malingerer," labels that could be extremely damaging in the hands of later employers or creditors. Clinicians who gossip about patients over coffee or in elevators put themselves at risk of liability on the grounds of defamation or breach of confidentiality.

Defenses against defamation include *substantial truth* and *conditional privilege.* Conditional privilege allows communication when both parties have a duty and an interest to receive and report such matters. For example, when one doctor refers a patient to another, conditional privilege in most jurisdictions allows the two doctors to discuss the patient's condition. (However, a prudent outpatient practice is to have the referring doctor have the patient sign a release.) No such privilege applies to those who have no such duty and interest. Testimony given in court or provided to the

court in documents such as medical reports or medical records attract *absolute privilege* insofar as they refer to the broadly defined matter at issue. *Malice,* if proven, destroys conditional privilege. Malice is substantiated by the author's evident self-interest, excessive distribution of the defamatory material, reckless disregard of the truth, or the vituperative style of the documents involved in the case.

Improper Treatment

Failure to Obtain Informed Consent

The doctrine of informed consent is founded on the constitutional right of the individual to control what is done to his or her own body (39). A patient cannot give informed consent unless he or she has (a) *sufficient information* on which to base a decision, (b) *mental competency* to make a rational decision, and (c) freedom to exercise *voluntary choice.* Almost all states require informed consent, and psychiatrists are also ethically bound to obtain it.

The physician must therefore disclose sufficient information to enable the patient, or the patient's legal representative, to weigh all material pros and cons. How much is that? The earlier "professional" standard (40,41) referred to *what a reasonable medical practitioner would disclose* under similar circumstances. Following two 1972 cases, *Canterbury v. Spence* (42) and *Cobbs v. Grant* (43), some jurisdictions may have adopted the "patient" standard, that is, *as much information as a reasonable patient would require* to make a rational decision under similar circumstances. *Canterbury* and other cases suggest that the physician should discuss the following matters with the patient:

1. The nature of the condition that requires treatment
2. The nature, purpose, and benefits of the proposed treatment, and the probability that it will succeed
3. The risks and consequences of the proposed treatment
4. Alternatives to the proposed treatment (including no treatment) and their attendant risks and consequences
5. The prognosis with and without the proposed treatment

The courts have held that *not all risks need be disclosed—only the material ones.* Unfortunately, there are no clear guidelines concerning what is "material," except to suggest that, even if the likelihood be slight, the more serious the risk, the greater the probability that it should be discussed. *A risk is material when a reasonable person would be likely to attach significance to the risk or cluster of risks.* Risk is linked not only to the procedure but also to the physician and his or her competence to perform the procedure (e.g., if the physician has alcoholism or suffers from human immunodeficiency virus infection). The plaintiff must prove that nondisclosure of material risk caused the injury of which he or she complains. Some

courts require that the plaintiff prove that a reasonable person would have refused the procedure had the risks been disclosed.

Therapeutic privilege countervails the clinician’s duty to disclose. The physician is obliged to protect a vulnerable patient from the emotional trauma that could be sustained if upsetting risks were prematurely revealed. However, therapeutic privilege should never be invoked merely because the clinician fears that, if apprised of the facts, the patient would reject a desirable treatment. If the clinician proposes to limit disclosure on the ground of therapeutic privilege, clear documentation and expert consultation are required concerning the patient’s exceptional sensitivity.

Consent is not required for emergency treatment in which the harm from failure to treat is imminent and outweighs the potential danger of the treatment. However, if possible, a relative’s consent should be obtained.

For most children and adolescents, informed consent of a parent or guardian is necessary for psychiatric treatment. In treating a child whose parents are divorced, the clinician should be sure that the parent requesting treatment is legally empowered to give consent. It is generally prudent to keep a copy of the legal custody order in the chart. On a clinical basis, it is generally best to obtain the consent and participation of both divorced parents. Problems can arise if both divorced parents have the power to consent, and one consents but the other refuses. In that case, the clinician should have the requesting parent obtain court authorization for the decision to pursue treatment.

In some cases, minors can consent to treatment on their own behalf. Competence is extended to emancipated minors. When should an unemancipated minor be regarded as sufficiently mature to participate in health care decisions? It depends on the jurisdiction and the condition being treated. All states allow minors to seek treatment for venereal disease. Most allow treatment for substance abuse. Landmark federal decisions (44,45) extended to “mature minors” the right to make health decisions concerning contraception and abortion, and required the availability of a judicial bypass procedure for minors who are not mature, but they left unclear what a mature minor was. Many states have “mature minor” rules which allow “mature” youth to seek treatment on their own. In some jurisdictions, “mature minor” is undefined, while in others it is defined by statute. Some states allow adolescents to seek outpatient psychiatric care. The present situation is very confused, and the practitioner should ascertain the law on the matter in his or her own state. The minor’s ability to consent, however, does not generally require the parents to pay for treatment, so youth obtaining psychiatric treatment on their own remains fairly rare. Although it may not be legally required, the desirability of promoting a treatment alliance suggests that it is judicious to promote the understanding and cooperation of all minors mature enough to comprehend. For patients more than 13 years of age, it is prudent to obtain formal assent.

The third element of informed consent, *voluntariness,* is easily compromised.

True voluntary consent requires that the patient be free of coercion. However, even a mature minor can be susceptible to threat, cajolement, bribery, or false inducement by parents, physicians, or hospital staff. The inmates of correctional institutions and psychiatric hospitals are particularly vulnerable to therapeutic coercion.

Problems with Admission

A physician who admits a patient to a psychiatric hospital without proper evaluation may be sued for *negligent diagnosis* or *false imprisonment.* A falsely imprisoned plaintiff may recover damages for *loss of dignity* and *emotional distress.* Ignorance of the mental health statutes is no defense; failure to comply with statutory requirements could be actionable. For example, in *Johnson v. Greer* (46), a patient recovered damages after being forcibly detained in hospital for several days beyond the 24 hours permitted on an emergency warrant. Malice, spite, ulterior motive, bad faith, or fraud during involuntary hospitalization could also result in damages for false imprisonment or *malicious prosecution* (47). Parents or guardians may admit unemancipated minors against their will, and health care providers should be able to rely on parental consent (47,48). However, the psychiatric justification for admission should be carefully documented.

Negligent Diagnosis

The physician must distinguish organic disease from functional disorders and, within the latter, must differentiate the major psychoses from each other and from other conditions. The physician who admits patients to a psychiatric hospital must be alert for signs that could indicate a toxic condition. In *Hirschberg v. State* (49), for example, a patient who had taken an overdose of salicylates died after having been hospitalized without adequate physical examination, special investigations, or proper precautions. The hospital was found liable.

The physician who fails to diagnose the patient accurately (e.g., by missing psychosis when it is present or by confusing bipolar disorder with schizophrenia) may found treatment on a false premise and thus may be open to a liability suit. However, there have been few actions on these grounds. Lawyers have been reluctant to pursue such cases in view of the reputedly widely varying expert opinion concerning the most appropriate treatment for different psychiatric conditions. As child and adolescent psychiatry becomes more empirically based, it is likely that such actions will increase in frequency.

Psychotherapy

There are so many schools of psychotherapy that failure to use a particular type of therapy or not conducting psychotherapy very skillfully seldom gives rise to a

successful malpractice action for several reasons. There is a lack of consensus in the field as to appropriate methods. It is difficult to prove harm as a result of negligent psychotherapy, because mental injury is hard to substantiate when the plaintiff was already emotionally disturbed before the alleged negligence. In the 1990s, however, suits involving allegations that recovered memories of abuse were "implanted" by therapists became frequent, and some led to large jury verdicts or settlements (50). In the highly publicized *Ramona* case (51) the father of a patient was allowed to sue on his own behalf for damages allegedly flowing from memories implanted in his daughter because the court found that he was a "direct victim" of the psychotherapy. The "direct victim" theory gives rise to many problems, such as who may sue and what the nature of the victim–plaintiff's relationship to the therapist must be (52), and is particularly an issue in child psychiatry because of the therapist's involvement with parents. The direct victim test has not been adopted in many states other than California. In a variant of this genre, the patient sues the therapist for failing to recognize that dissociative identity disorder is confabulatory or for accepting uncritically the patient's recovered memories of abuse.

Sexual Exploitation and the Tort of Outrage

Expert testimony is not required to substantiate the impropriety of sexually molesting a patient. As an intentional tort, *res ipsa loquitur* ("the thing speaks for itself"), and the burden of proof shifts to the defendant. In *Roy v. Hartogs* (53), the court held that public policy protected patients from such malicious abuses of authority, power, and fiduciary trust. The perpetrator faces criminal sanctions for rape, aggravated assault, or child abuse, as well as civil actions for malpractice or battery (unconsented touching). Most malpractice policies will cover the cost of a defense if the clinician denies that sexual contact occurred, but exclude payment for damages for a sexual relationship with a patient. Liability for improper sexual relations may extend beyond the patient to others involved, such as the spouses of patients so harmed. Residual transference has persuaded courts that cessation of treatment does not open the door to a sexual relationship. Indeed, *negligent management of the transference* is often adopted as the theory behind the action for damages.

The tort of *outrage* refers to the intentional infliction of severe emotional distress on a patient, as a result of reckless and intolerable behavior. For example, in *Abraham v. Zaslow* (54), damages were awarded to a woman who had sustained bruising and renal failure after exposure to "rage-reduction therapy," an intrusive intervention involving several hours of physical restraint, poking, tickling, and verbal insult. Patients have a right to expect that clinicians will adhere to established methods of treatment. If exceptional methods are proposed, full informed consent is required, supportive consultation from a colleague would be advisable, and adequate reference to the scientific literature should be made.

Medication

The points in the medication of a patient at which negligence is most likely to occur are as follows:

1. The diagnosis of the psychiatric disorder
2. The adoption of an appropriate rationale for drug therapy
3. The choice of a particular drug to treat the patient's psychiatric disorder
4. Inquiry concerning a past history of excessive therapeutic response, severe side effects, or allergic reaction to the drug in question or to related drugs
5. The search for coexistent medical conditions that would contraindicate the medication in question or would indicate the need for caution in its use
6. Obtaining informed consent
7. The administration of an appropriate dose of the drug in question, by an approved route
8. The prescription of drugs in combination, or the addition of a drug or drugs to an existing medication regimen
9. The choice of a drug not approved by the U.S. Food and Drug Administration or the use of a drug in a way, or for a purpose, that deviates from that recommended in the package insert or *Physician's Desk Reference* (PDR)
10. Monitoring the therapeutic effect and side effects of the medication
11. Ceasing the medication after a therapeutic effect has been achieved or maintaining long-term medication at the lowest effective dosage

Decision to Medicate

In *Osheroff v. Chestnut Lodge et al.* (55), suit was brought against a private hospital for negligent failure to disclose all treatment alternatives. The plaintiff, who suffered from mixed affective and personality disorder, had been treated for several months with individual psychotherapy. After transfer to a different hospital, he responded to antidepressant medication within a few weeks. Several eminent psychiatrists testified for the plaintiff that antidepressant medication was the treatment of choice, and the plaintiff had had insufficient opportunity to consider it as a treatment alternative. The suit was settled out of court in favor of the plaintiff. Such cases are less common with children because the use of medication is more controversial in this age group.

Inappropriate Rationale for Treatment

Psychotropic drugs are sometimes prescribed to control inmates in correctional or intellectual disability institutions and may be overused in foster care situations where consent is being provided by a protective services worker who is not very familiar with the patient. These situations warrant close scrutiny; the physician may have been induced to medicate the patient by the urgings of harassed staff, rather than by the

medical needs of the patient, a practice that has been specifically criticized in at least one class action suit (56) and one malpractice case (57).

Choice of an Inappropriate or Unapproved Drug or Route of Administration

This kind of error occurs when the physician orders a drug that is inadequate to treat the patient's disorder (a benzodiazepine for major depressive disorder) or when the physician prescribes a drug for which there are less risky alternatives (a neuroleptic for anxiety disorder). A different problem arises when the clinician prescribes a drug not approved by the Food and Drug Administration. Undoubtedly, the risk of malpractice is greater if approved guidelines have not been followed. However, because of the great expense of generating data to persuade the FDA to approve an indication for a drug's use in children, more than half of all PDR entries lack labeling with pediatric information (58). Courts generally find that the PDR does not set the standard of practice, and expert testimony is necessary to determine whether a particular use is an accepted treatment. Usage that is more experimental or investigational requires providing considerably more information about benefits, risks, and alternatives to obtain informed consent.

An intravenous or intramuscular route of administration carries an increased risk of excessive or adverse response. This is particularly likely if the patient is predisposed to side effects as a result of hepatic, renal, cardiac, or brain dysfunction. The clinician should be cautious if such conditions are detected. Parenteral administration should generally be reserved for emergencies or long-term depot treatment.

Over the past 5 years, there has been increasing concern that many children in state custody, both in foster care and in juvenile detention facilities, are being overmedicated. The media have highlighted the stories of young children who have received numerous concurrent medications, including multiple antipsychotics, and argued that such medications are being used inappropriately for behavioral control rather than treatment. Attention to this problem has led to calls for increased regulation of prescribing to this vulnerable population. The American Academy of Child and Adolescent Psychiatry (AACAP) has created a practice parameter on the topic (59), and clinicians working with this difficult population are well advised to keep current with their state's regulations and the AACAP guidelines.

Failure to Obtain a Medication History

The patient's past medication history should be ascertained by interview, by review of medical records, and by telephone contact, if required, with other clinicians. The physician may be held liable for excessive side effects, allergic reactions, idiosyncratic responses, or drug interactions, if these had been foreseeable.

Failure to Detect Contraindicative Conditions

The physician may fail to check for conditions or disorders that would render the patient vulnerable to severe side effects. For example, pre-existing hypothyroidism may be overlooked when lithium is prescribed. Different classes of psychotropic drug require different assessments prior to prescribing. If a contraindicative condition is uncovered but the medication is still considered potentially justified, a risk-to-benefit analysis should be documented, expert consultation should be obtained, and specific informed consent should be recorded. Hospitals should mandate, as policy, standard diagnostic workups for all psychotropic drugs. Since a very high proportion of adolescent pregnancies are unplanned and psychotropic drugs cross the placenta, when prescribing medication to an adolescent girl, the clinician should document pregnancy status and use of contraception.

Forcible Administration

The involuntary commitment of a patient to a psychiatric hospital does not permit involuntary medication, except in narrowly defined circumstances, generally having to do with the safety of the patient or others. Forcible medication can place the practitioner at risk of an action for the intentional tort of battery. The legal doctrine most pertinent to this issue, *the right to refuse treatment,* has been most clearly articulated in two convoluted cases, *Rennie v. Klein* (1981) (60) and *Rogers v. Commissioner of Mental Health* (61). In *Rennie,* a New Jersey case, it was determined that the mentally ill had a sufficient liberty interest to require due process before treatment was forcibly administered, but due process was satisfied by an in-hospital review. In considering this case, the U.S. Supreme Court deferred to the professionalization standard articulated in *Youngberg v. Romeo* (1982) (62), in effect declining to uphold a constitutional right to refuse treatment. In *Rogers,* the Massachusetts Supreme Court held that involuntarily committed patients should be presumed competent to refuse treatment except in emergencies. An “emergency” was defined as a situation fraught with the need to prevent violence or associated with the likelihood that the patient’s health would significantly deteriorate without treatment. In nonemergency situations, forcible treatment may be administered only after a judicial hearing in which the court approves a “substituted judgment” treatment plan. “Substituted judgment” requires the court to determine what the patient would have decided if he or she were competent.

The failure of the U.S. Supreme Court to clarify this matter means that each state must make its own determination of the boundaries of the right to refuse treatment. The legal situation with regard to children is unclear. The right to refuse treatment apparently extends to the legal guardians of minors, to emancipated minors, and to those minors otherwise empowered to consent. What of the mature minor? Arguably, except in emergencies, the clinician should seek the consent of both mature minor and

parent before starting treatment. If the mature minor refuses treatment, and the treatment is regarded vital, a judicial determination of competence should be requested.

Failure to Monitor Treatment

Adequate monitoring of drug effects requires baseline and regular mental status examinations, physical examinations, vital signs, and laboratory testing, in accordance with the pharmacology of the drug and its potential side effects. "Drug holidays" should be considered if long-term medication is required. Physicians run a serious risk if they write "as-needed" orders for potent drugs, if they telephone prescriptions into a pharmacy without examining their patients, or if they provide multiple repeat refills without proper monitoring. In 2004, in response to concerns that SSRIs increase reported suicidal thinking and behavior in some children and adolescents, the FDA issued a "black box" warning, which was then revised in 2007 to say patients started on an SSRI "should be monitored appropriately and observed closely for clinical worsening, suicidality, or unusual changes in behavior" (63). In the event that a child or adolescent commits suicide shortly after beginning an SSRI, a defendant psychiatrist would likely have a difficult time persuading a jury that close monitoring was not necessary. Recent actions by national regulatory agencies in the United States, United Kingdom, and Canada suggest that psychotropic medications are being exposed to increased regulatory scrutiny.

Abandonment

Psychiatrists are most at risk of liability when they terminate the treatment of patients without adequate safeguards, when they are unavailable and either no covering physician is provided or the covering physician has not been given sufficient information, or when adequate steps are not taken to protect endangered third parties.

The physician has the duty to provide continued care, as long as needed, until the doctor–patient relationship is terminated. This relationship may be severed by mutual consent or by the patient. However, unilateral termination of care by the clinician, if abrupt or premature, may put him or her at risk of breach of contract should harm, such as suicide, befall the patient. Failure to provide a telephone number for a disturbed patient to call, failure to provide adequate substitute care during absences, or failure to convey adequate precautionary information to substitute physicians may all be construed as abandonment if the patient is found to have suffered harm as a consequence.

When is the therapist warranted in unilaterally terminating the relationship? Lack of cooperation or threatening behavior may justify termination; failure to pay the bill does not (64). If the clinician does decide to terminate the relationship, the following

safeguards are required (28):

1. The reason for the termination should be discussed with the patient and parents. The clinician should give at least 1 month's notice of termination, to allow the patient to locate another therapist.
2. The patient and parents should be provided with the names and telephone numbers of alternative therapists or agencies.
3. The clinician should mail to the patient and parents a certified letter (return receipt requested) reflecting this discussion and containing the reasons for termination. The letter should also convey the names and telephone numbers of alternative clinicians or agencies.

TEACHING, RESEARCH, AND PUBLICATION

The torts of *invasion of privacy, breach of confidentiality,* and *defamation* are the liability risks most commonly incurred by teachers, researchers, and writers.

These torts stem from the ethical, contractual, and (in some jurisdictions) statutory obligation of the clinician not to disclose private information that should be kept within the doctor–patient relationship. In invasion of privacy, the plaintiff alleges that details from his or her private life have been publicized. This may occur, for example, if a clinician publishes an article in which the identity of the subject is insufficiently disguised. It has been held that a patient undergoing psychotherapy cannot give proper informed consent to the publication of a book concerning the treatment (65).

A patient has the right to bar nonessential onlookers when he or she is being examined or treated or when his or her case is discussed. The teacher should seek informed consent before exposing patients to case conferences or discussing cases for teaching purposes. The use of video recordings for teaching necessitates written informed consent, the continuation of which should be requested on a yearly basis.

Research with children poses complex ethical issues over and above issues with adults because of children's vulnerability and lack of legal competence. Federal law includes special protections for children involved in federally sponsored research (66). These include the requirement that, in addition to the parent's consent, the child's assent is required for participation for research that is not expected to benefit the child (assuming the child can give assent). The Privacy Rule authorized by HIPAA carries further requirements for protecting the privacy of actual or prospective research subjects. Institutional review boards (IRB) in universities and most organizations have adopted these principles for all research they review, even if technically the research would not be governed by federal rules. Any practitioner involved in research would be well advised to meet these standards. If research procedures are later questioned, especially if an adverse event befalls a research subject, documentation of approval by an IRB is a crucial component in

demonstrating the research was undertaken thoughtfully and with due regard to the well-being of the research subjects.

COMPLAINTS TO OTHER REGULATORY BODIES

Malpractice cases are not the only arena in which care of a child or adolescent may be scrutinized. Complaints may be made to state licensing boards, professional ethics committees, and, for HIPAA violations, to the Office of Civil Rights of DHHS. Unlike in a malpractice case, harm to the patient does not need to be proved for a complaint to be found justified: all that is needed is proof of unethical or incompetent behavior or violation of a regulation. For example, if a clinician is found to have practiced while intoxicated, he can be sanctioned even if his actual care has not been shown to be poor. Furthermore, the range of professional work that can be scrutinized is wider, because a doctor–patient relationship is not necessary for a complaint to go forward. For example, child psychiatrists who conduct child custody evaluations on court order are generally immune from malpractice suit, both because such evaluations, like most forensic evaluations, do not create a doctor–patient relationship, and because the evaluator is an agent of the court and so usually has the immunity of other court personnel. However, disgruntled parents are free to pursue complaints to ethics committees and state licensing boards, and such grievances are not uncommon.

From the perspective of the investigated doctor, complaints to these agencies trigger a process that is similar in many ways to being sued. Sometimes, particularly with ethics committee investigations, the psychiatrist may feel that the whole matter can be disposed of informally by discussion with members of the committee and submitting records for review. Unless the clinician is extremely confident or very familiar with the proceedings, however, he or she is well advised to obtain an attorney before proceeding, rather than run the risk of making admissions that may later prove damaging, or in agreeing to waive due process protections in order to “wrap this up in a hurry.” Many malpractice insurance policies cover the cost of attorney representation in licensing board investigations. While money is not at stake directly (although results of these investigations are often admissible in later malpractice actions), the psychiatrist’s license to practice medicine may be threatened, and one should proceed cautiously.

RISK MANAGEMENT IN CHILD PSYCHIATRY

Clinical practice is fraught with error, and error can have serious consequences. Confronted by the catalog of litigation in this chapter, even the insouciant may quail. However, defensive psychiatry is no answer, because overly timid treatment can also

put the clinician at risk of negligent malpractice. What, then, is the best way to avoid litigation? General risk management principles that apply to adult psychiatry, such as the importance of clear communication with patients and parents and good documentation by the clinician apply to work with children and adolescents as well. Some special considerations that apply to child and adolescent psychiatry are shown in Table 7.4.4.2. The best precaution is to practice careful medicine while fully apprising the patient and family of the diagnosis, treatment plan, and progress of therapy. Many malpractice suits arise from neglect of this simple principle. Hospitals provide many opportunities for failed communication, particularly when the attending physician delegates to other members of the team the responsibility for keeping parents informed of their children's progress. A good therapeutic alliance is the key to good medicine and the avoidance of lawsuits. Used for this purpose, informed consent can be transformed from an empty legalism into the foundation of a true collaboration.

Documentation

The clinician should keep a good record of the rationale for treatment. Progress notes should be timely, regular, dated, and signed. Gutheil, in his classic 1980 article on paranoia and progress notes (67), recommends imagining a plaintiff attorney looking over your shoulder while writing progress notes. Issues that potentially may come to court, such as those described above, should be documented fully. If you disagree with the diagnosis, investigation, or treatment plan in the record, respectfully note that you disagree and insert your amended diagnosis and plan. If you merely sign off on a trainee's notes, you could be concurring with erroneous observations, diagnosis, or treatment. One of the most common errors is to raise a diagnostic question but not follow through by investigating it or, having ordered an investigative test, to not follow up on the results.

Note any discrepancies between the nurses', the therapist's, and the physician's progress notes. If there is such a discrepancy, try to account for it. Do not allow a nursing progress note concerning suicide risk to go unremarked.

If you detect an error in your notes, do not erase it. Draw a line through the error, write "error," and date and sign your correction in the margin. Do not criticize or argue with other professionals or agencies in your notes, and avoid gratuitous or extravagant commentary ("This child has had an appalling home life"). Do not record psychodynamic speculations in the clinical record; those unconscious incestuous strivings may come back to haunt you. You may consider keeping your psychotherapy *process notes* separate from the official record of therapy *progress notes*.

TABLE 7.4.4.2

RISK MANAGEMENT PRINCIPLES

General Principle	Special Consideration in Child and Adolescent Work	Example of Potential Problem
Open communication	Clear understanding of minor's confidentiality and exceptions	Parents have right to see chart Parents need to be told of dangerous situations
Clarity of role definition	Whether the child or the whole family is the patient	In family work, there may be a doctor–patient relationship with each person in the family
Need to obtain informed consent	Assent from minor is useful; consent from parents is usually required	In nontraditional family or postdivorce situations, need to be sure which parent(s) have authority to consent
Appropriate medication use	Much use is off label	Insufficient explanation of possible side effects
Compliance and cooperation with treatment	May be reduced by immaturity or minor's lack of agreement	Jury may see immature child as less responsible than an adult and so attribute more responsibility for safety to the clinician
Documentation of treatment	Documentation of communications with collateral sources (parents, school) is important	Failure to document telling parents that their son had some suicidal symptoms
Careful risk assessment	Risk factors less researched and less predictive than with adults Ratio of suicidal ideation to completed suicide is much higher than with adults	Unforeseen impulsive suicide

Dangerousness Assessment

A risk–resource analysis should be conducted whenever a patient presents a risk of violence to self or others. Such an assessment is most likely to be required in the following circumstances: when the risk of violence is raised during outpatient evaluation or treatment; when a potentially violent patient presents for admission to hospital; when the leave or discharge from hospital of a potentially violent patient is being considered; or when such a patient elopes. Areas of assessment when considering violence toward others commonly cited in the literature are shown in Table 7.4.4.3.

Predatory violence, that is, violence that is planned, is more difficult to assess because the youth has a clear motive to conceal his thinking. In the wake of highly publicized school shootings, many schools have developed the so-called "zero tolerance" policies for direct or implied threats of school violence that may be triggered when a child or adolescent makes a threat, brings a weapon to school, or writes a story that includes violence toward peers. In such situations, schools frequently require a psychological evaluation before allowing a child to return. The clinician should be aware that a single individual assessment alone is of very limited value in these situations, and only tentative conclusions about dangerousness should be drawn. More accurate evaluations require corroborative interviews, especially

with friends of the evaluated youth, to assess whether the youth is on a path of escalating interest and planning of hurting others. In such interviews, one is looking not only for direct threats and violent ideation, but for "leakage," a spilling over of preoccupation with violence, such as might be found in diaries, being fascinated with weapons, following prospective victims, drawing plans of the school, etc. (68,69).

Treatment

Before a particular treatment is commenced, be careful to check that the patient harbors no conditions and is taking no drugs that would contraindicate it, and inquire about previous allergic or idiosyncratic reactions to drugs. For drugs with known teratogenic effects in early pregnancy, such as sodium divalproex, the rationale for use in girls should be carefully documented, even for a girl who states she is not planning to become pregnant. Avoid polypharmacy. Monitor the progress of medication regularly. In patients taking long-term medication, "drug holidays" should be considered. Unless there are good reasons for departing from them, follow recommended guidelines for dosage and administration. Avoid prescribing medication "as needed" and automatic refills, and be careful of telephone requests for repeat prescriptions. If the suicide risk is serious, only small amounts of a potentially lethal drug should be prescribed. Hospitals should check that potentially suicidal patients are not cheating, concealing, and hoarding medication.

TABLE 7.4.4.3

AREAS FOR ASSESSMENT OF RISK OF VIOLENCE TO OTHERS

- Past history of violent threats or actions
- Nature of Threat
  - Direct threat
  - Has potential victim been bullied or provoked patient?
  - Plan for harming the victim
  - Access to lethal weapons?
  - Leakage of preoccupation with violence in journals, web surfing, and writings
  - Taking steps toward action, such as following or stalking victim, obtaining a weapon, rehearsing an attack
  - Threat communicated to others, especially peers
- Past History
  - History of being abused
  - History of alcohol or drug abuse
- Demographic Factors
  - Late adolescent
  - Male
  - Disadvantaged ethnic groups with a cultural tradition of masculine defensiveness
- Psychological Factors
  - Copes with anxiety or hostility by externalizing or projecting it in the form of impulsive, explosive actions, suspicious vigilance, or frank persecutory delusions
  - Command hallucinations that instruct the patient to take violent action or that threaten violence to the patient or his or her family
  - Inner controls against violent actions subjectively or objectively reduced

Strong inner urge to be violent
Social environment
Family psychopathology in the form of rejection, neglect, physical or sexual abuse, or family violence

When a patient is admitted to the hospital, the degree of risk of suicide or violence should be assessed, and each degree of risk should be linked to a set of nursing precautions that are automatically activated when the clinician indicates the degree of risk. Every attempt should be made to obtain past records and to scan them for risk factors.

If you are unavailable in case of emergency during treatment, the name of a fully informed substitute physician should be provided to the patient. Do not terminate treatment unilaterally without preparing the patient, giving adequate notice, and providing him or her with the names of other clinicians or agencies that could help.

In outpatient practice, the duty to protect is precipitated when the patient makes a specific threat to harm a specified victim. When possible, incorporate the protection in therapy. Psychotherapy, hospitalization, and medication may be both more protective and more therapeutic than warning the foreseeable victim or alerting the police.

Be vigilant to avoid unauthorized disclosure of confidential information to external agencies, do not gossip about patients, and do not publish articles about patients without adequately disguising their identity. Obtain the parents' consent before releasing reports to external agencies. Blanket consent forms, obtained during the rush of admission, may not hold water legally.

Identified High-Risk Situations

There are often clinical situations in which the physician recognizes a higher than usual risk of an adverse outcome, such as when a chronically suicidal adolescent is to be discharged from the hospital, or standard medications have been tried and failed, and a less tested medication with the potential for serious side effects is being considered. A number of strategies can lessen the liability risk in managing such situations. First, document in more than usual detail the pros and cons of the intervention being considered. Second, be especially attentive to informed consent issues, discuss such issues fully with the parent or guardian, document the discussion, and, if medications are involved, have a parent sign a written consent form. Third, when in doubt, shout! (70) Get a second opinion and have it documented. In case of a malpractice suit, the test will be what a reasonable clinician would have done under the circumstances. A consulting clinician's contemporaneous second opinion will likely carry greater weight than the opinion of a hired expert who wasn't there peering through the retrospectoscope with full knowledge of the subsequent events.

CONCLUSION

CONCLUSION

When Bellamy (71) examined appellate psychiatric malpractice cases in the 15 years after World War II, he could identify 18 cases, none of which involved child or adolescent patients. The situation is not so rosy today, but defendant doctors still win most cases. The law has no wish to penalize physicians for honest errors. Its purpose is to protect patients from being harmed by reckless, careless, or incompetent clinical practice, and if they have been so harmed, to compensate them for injury. In most successful suits for negligent malpractice, the errors are glaring. Attention to the safeguards described in this chapter will protect clinicians from litigation while allowing them to practice nondefensive psychiatry.

POSTSCRIPT ■ LOOKING BACK, DREAMING FORWARD: REFLECTIONS ON THE HISTORY OF CHILD PSYCHIATRY

LEON EISENBERG

Anyone willing to write a chapter entitled Looking Back, Dreaming Forward must hesitate on recalling Yogi Berra's quip, "The future ain't what it used to be." However cloudy my vision forward, what I see when I look back (it's 60 years since my graduation) may be instructive for younger readers (by now almost everyone is younger than I am). What I see when I remember the child psychiatry of the 1950s is both ignorance (for which we cannot be blamed) and arrogance (for which we can). As Bertolt Brecht has Galileo say in his play:

> One of the chief causes of poverty in science is imaginary wealth. The purpose of science is not to open the door to an infinitude of wisdom, but to set some limits on the infinitude of error (1).

When I was trained by Leo Kanner, there was no subspe-cialty certification, and hence no ABPN-approved residencies. In the 1950s, most departments of psychiatry were heavily psychoanalytic in orientation; departments of psychology were behavioristic; the word *neuroscience* had yet to be coined. When I say I was trained by Kanner, I mean that quite literally. I acknowledge that I did gain a great deal of practical knowledge from the one social worker (Barbara Ashenden) and the one psychologist (Charlotte Waskowitz) on the staff, but neither was academic in orientation. When I joined the full-time staff of the Children's Psychiatric Service after completing my training, I effectively doubled the number of psychiatrists.

Leo Kanner was a polymath. If there is such a thing as *eidetic* imagery, he had it. He could picture in his mind the page on which he had read a poem in high school. He recalled the names of teachers who had attended his evening adult education classes at Hopkins when he saw them on the city streets. They were astonished to be remembered by name (and often he added the names of their seatmates) 5 or 10 years after a one-semester course (and I was equally astonished as I looked on!). A graduate of the Sophien-Gymnasium in Berlin who had earned his M.D. from the University of Berlin with a thesis on electrocardiography, he knew classical Greek and Latin (and frequently quoted Homer and Virgil). As a child he had learned Polish, Hebrew, and German, went on to learn English, and had familiarized himself

with other languages as well. He was vain enough to display his erudition with multilingual puns that kept a monolingual American (with only remnants of high school Latin and German) hopping trying to figure them out.

His principal mode of teaching was extending to me the privilege of sitting in on his consultations with patients and families. The "price" for the privilege was taking notes and writing up the case report for the formal record (once he had come to trust the fidelity of my accounts). And it was an extraordinary privilege. He was polite and gentle but his questions were penetrating. He listened intently. He was unfailingly courteous, even to the most arrogant and dismissive parents. He charmed children and adolescents alike. His secret psychiatric technique (no longer permissible) was smoking a cigar. He blew lingering smoke rings (in those days, no one knew of the risks of second-hand smoke; those who objected to smoking did so on aesthetic grounds). The children were invariably fascinated. While he saw the parents, the clinic psychologist did a Binet or a WISC on the youngster and provided a brief and usually quite insightful report on her findings before he met the parents again. He wrapped up the 2- to 3-hour sessions with a sagacious review of what he had learned, with what he thought might be helpful to child and family, and with appropriate referrals (his was primarily a consulting practice). Then, he and I would have another 30 minutes together. I was free to pose any questions I wanted. I was encouraged to challenge his conclusions. I often did but usually came around to his position when he mustered the grounds for it.

During the other 4½ days of the week, I saw and treated clinic patients referred from pediatrics and, with the other fellows and occasional rotating pediatric residents, participated in a weekly case conference chaired by Dr. Kanner with the social worker and psychologist in attendance. There was no journal club, no regular supervision. It was catch as catch can with colleagues.

Kanner had come to America in 1924 amid the economic chaos in Berlin for a job in the State Hospital in Yankton, South Dakota (German inflation was on an exponential curve). In this unlikely setting, he found a way to do research and to publish several papers, one of which (on the rarity of general paresis among Native Americans) attracted the attention of Kraepelin, who visited Yankton to meet Kanner. In 1928, he applied for and received a Commonwealth Foundation Fellowship from Adolf Meyer, then the doyen of American psychiatry, at the Henry Phipps Clinic of the Johns Hopkins Hospital. At the completion of the 2-year fellowship, Meyer and Edwards A. Park, the Professor of Pediatrics, chose Leo Kanner to inaugurate a new clinic in pediatrics, charged with "investigating the rank and file of patients in the pediatric clinic for the form(ul)ation of psychiatric problems, the mastery of which should be made accessible to the pediatrician to serve him as the psychopathological principles in dealing with children."

The clinic was initiated in 1930 with support from the Rockefeller Foundation. His office was a small pediatric examining room with a sink and a table. Five years

later, based on his intensive study of the world literature and his clinical experience, Kanner wrote the first English-language textbook on child psychiatry (2). Its first edition paid homage to Meyer's psychobiological terminology, but by the second (3), the Meyerian neologisms were abandoned. Kanner's most outstanding and lasting contribution was the identification of the syndrome he called "autistic disturbances of affective contact" (4). On the basis of 11 patients who had been brought to him because of their unusual psychopathology, he formulated the characteristics of a syndrome still identified by these very features. In Michael Rutter's words (5): "Kanner's paper was a model of clarity in its combination of systematic, thorough, and objective observation with deep clinical understanding and appreciation of the personal problems faced by each child, and his family: . . . Nearly all the basic points made in the original paper have been amply confirmed by other writers."

Kanner had concluded his 1943 article with the statement: "Here we seem to have a pure culture example of an inborn autistic disturbance of affective contact." That conclusion, at a time when child psychiatric disorders were uniformly attributed to psychogenic causes, left him out on a limb and probably delayed widespread acceptance of the syndrome as a clinical entity. His syndrome remains unique.

MENTAL RETARDATION

The very terms in the official classification for the mentally retarded offend today's sensibilities. The terms ran from feebleminded to moron to imbecile to idiot. Down syndrome was still known as Mongolian idiocy, a label reflecting Langdon-Down's belief that it was an atavistic throwback to a more primitive "Mongolian race" (6). We did know that risk increased with the mother's age, but trisomy 21 was not identified until the late 1950s (7,8). That is hardly surprising, given that the correct human chromosome number was not established until 1948! Whatever the terminology and whatever the ignorance about pathophysiology, what remains distressing is that most child guidance clinics of the '50s and '60s screened out retarded children as if retardation excluded treatable psychiatric disorders. A recent study of an epidemiological cohort of almost 600 children with intellectual disability has provided documentation of the substantial and persistent level of psychopathology and the need for effective interventions (9).

Few things epitomize Kanner's personal commitment to the rights of all children more than his concern for the "feebleminded" at a time when most psychiatrists assiduously excluded them from their clinics and offices. The Superintendent of the Maryland State Training School for the Retarded, knowing of Kanner's concern for such patients, appealed to Leo Kanner for help in controlling an appalling problem. Female patients were being removed from the training school by court orders and were being exploited in the community for cheap domestic labor. The superintendent was at his wits' end; he simply didn't know what to do. With the assistance of Miss

Mabel F. Kraus, a social worker, Kanner (10) did a followup study on 166 patients who had been released from the school via habeas corpus writs secured by lawyers over the previous two decades. Three-quarters of these releases had been obtained by enterprising attorneys who, for a fee, secured what were essentially indentured domestic servants for affluent Baltimore households; others had been claimed by relatives who suddenly appeared to manipulate estates that had been left them; a few were demanded by parents who, after years of neglect, asserted their "natural rights."

Kanner was able to follow 102, of whom only 13 were making even a modestly satisfactory adjustment in the community at the time of the study; 11 had died of illness and neglect before they reached 30; 17 had tuberculosis, syphilis, or gonorrhea; 29 were prostitutes; 8 had been committed to mental hospitals; and 6 were in prison. In total, these released patients had given birth to 165 offspring, 18 of whom had died from neglect, 30 of whom had been committed to orphanages, and 108 of whom tested at a "feebleminded level" when examined. The customary sequence had been a period of domestic servitude, followed by peremptory release when the young women proved to be inadequate as maids, and then a mournful hegira through the whorehouses and flophouses of the Baltimore slums. Few now remember Kanner's paper in the *American Journal of Psychiatry,* but in 1938, the study had a dramatic impact. The release of the information produced a double row of inch-high headlines across the front page of the April 8th edition of the *Baltimore Sun* and provided the impetus to end an evil practice that had arisen from the collusion of attorneys and judges against the valiant but unsuccessful opposition of the superintendent of the Training School. It is a study worth remembering (10). Clinical precision joined with social conscience in a clinical project with immediate benefit for the lives of a despised minority.

In 1942, amid the war against the Nazis, Foster Kennedy, a well known neurologist, published a paper in the *American Journal of Psychiatry* entitled: "The problem of social control of the congenital defective: Education, sterilization, euthanasia" (11). In it, he proposed that defective children with no future or hope of a worthwhile life "should be relieved of the agony of living," language remarkably similar to the Nazi policy to *end life unworthy of life.* In a vigorous response to Kennedy, Kanner (12) wrote: "Let us try to recall one single instance in the history of mankind when a feeble-minded individual or group of individuals was responsible for the retardation or persecution of humaneness and sciences. They who caused Galileo to be jailed were not feeble-minded. They who instituted the Inquisition were not mental defectives. The great man-made catastrophes resulting in wholesale slaughter and destruction were not started by idiots, imbeciles, morons, or borderlines. The one man, Schicklgruber, whose IQ is probably not below normal, has in a few years brought infinitely more disaster and suffering to this world than have all of the innumerable mental defectives of all countries and all generations combined."

Kanner's revulsion against euthanasia for the severely retarded was not universal; in the same issue of the *Journal* an unsigned editorial argued that the role of psychiatrists should be to persuade parents to agree to release their defective children from "the burden of living" (13). Euthanasia never became official policy, but sterilization was widespread in U.S. institutions for the mentally retarded.

EARLY RESEARCH ON THE HERITABILITY OF EARLY INFANTILE AUTISM

When Leo Kanner (4) first identified infantile autism as a diagnostic entity, he concluded that his patients had:

> … come into the world with an innate inability to form the usual, biologically provided affective contact with people, just as other children come into the world with innate physical or intellectual handicaps…. [W]e seem to have pure culture examples of inborn autistic disturbances of affective contact (p. 250).

Kanner believed that his emphasis on an "inborn" disturbance delayed the acceptance of early infantile autism as a clinical entity. Recognition of the impact of severe maternal deprivation on child development had brought psychogenesis to the fore (14–16). Psychiatry was dominated by Don Jackson's "schizophrenogenic mother" and Gregory Bateson's "double-bind" (17). When Kanner coined the term "refrigerator mother," the diagnosis of autism became more fashionable; it suggested that a "refrigerator mother" produced a "frozen child" (something he later regretted). Kanner was aware of the frequency of obsessional and schizoid traits among the parents and even suggested that the parents might be "successfully autistic adults." Indeed, in my paper on the fathers of autistic children I suggested that the severe obsessional traits and relative social isolation some displayed might represent a *forme fruste* of the complete entity (18). Thirty years later, Sula Wolff and her colleagues (19) compared the parents of autistic patients with the parents of other child psychiatric patients and confirmed Kanner's observations on the predominance of schizoid and socially gauche characteristics. But neither he nor I seriously pursued the genetic hypothesis. At Kanner's invitation, I reviewed the charts of his first 100 patients and found 131 siblings, of whom 3 were autistic (20). I did not have a clue about the significance of what I had found. All I knew of genetics was Mendelian; it was clear that Mendelian laws were not operative in autism. Autism, I concluded, was not inherited because it was not Mendelian. No one called attention to my error.

In the 1950s, there were no published data on the prevalence of autism; but assuredly we knew it was rare. It was not until 10 years later that modern child psychiatric epidemiology began with the Isle of Wight study by Rutter and his colleagues (21,22). In a total population of 2,200 children, they found only one

autistic child, a prevalence similar to the estimate of 4 to 5 per 10,000 published in the same year by Lotter (23). But I didn't understand what finding three autistic children among 131 sibs implied. The rate I observed among siblings was two orders of magnitude greater than expected and established a genetic risk. Not until the mid-1970s did Folstein and Rutter (24) provide unequivocal proof of inheritance by comparing the identical and fraternal cotwins of autistic probands in a total population sample. I call attention to my failure to understand the data I analyzed to remind readers that the prevalent concepts, ideas, and methods of any given era act as blinders to all but the very gifted.

"ADHD" IN THE 1950s

When my professional career began, what is now known as ADHD had not yet been recognized as a diagnostic entity. Symptoms of overactivity and inattentiveness existed, of course, but were allocated to such categories as "behavioral disorder," "minimal brain damage," "minimal brain dysfunction," or "post-encephalitic syndrome" (even though an episode of encephalitis had never been documented). The patients were not of much interest to most child guidance clinics because of the supposition of "organicity." The one symptomatic treatment that seemed to be as effective was dextroamphetamine. It was not in wide use and had never been put to an exacting test. Indeed, when the Psychopharmacology Service Center of the NIMH convened a conference in 1958 on Child Research in Psychopharmacology (25), "there was essentially no research on drugs in children" (26). Randomized controlled trials were being introduced into psychiatry in the late 1950s. Our research group at Hopkins received the first NIMH grant for RCTs on tranquilizers and stimulants for treating hyperkinesis in children (27). Tranquilizers proved to be worse than placebos (28), but stimulants were clearly effective (29), a finding that has been repeatedly confirmed.

What was entirely unexpected was the explosion in the use of these agents in subsequent decades for a condition that had been regarded as uncommon, so uncommon that the first edition of the APA *Diagnostic and Statistical Manual* (DSM I), published in 1952, had no such categories as hyperactivity or attention deficit disorder. In 1967, I participated in a World Health Organization Symposium on Diagnosis and Classification in Child Psychiatry (30). Mike Rutter and I had to argue vigorously for the inclusion of hyperkinesis as a syndrome. The other participants were highly skeptical of the diagnosis hyperkinesis. Most U.K. psychiatrists allocated it to the category "behavior disorder." We won the day, and hyperkinetic reaction of childhood appeared in DSM II in 1968; however, it was not until DSM III (1980) that attention deficit/hyperactivity disorder (ADHD) entered the official lexicon.

It is, of course, not possible to find data on rates before a given disease has

entered the official nomenclature. The Centers for Disease Control (31) estimate ADHD population prevalence based on parental reports from the National Survey of Children's Health in 2003 at about 4.4 million American children aged 4–17 years of age. More than 50% of those children (2.5 million) were reported currently to be taking medication for the disorder. The survey reports a remarkably wide difference in the percentage of children with ADHD between Colorado (~5.1%) and Alabama (~11.2%), with an overall U.S. average of about 7.8%. Can these disparities possibly be valid? Are there localized "epidemics" of ADHD or is it that there are epidemics of diagnosis? Do the variations reflect differences in the availability of specialists, in fashions in diagnosis, and in their administrative consequences in particular communities?

It is useful to recall, in this connection, Judy Rapoport's studies in the late 1970s. At the time, dextroamphetamine was labeled pharmacologically as a stimulant. Because hyperkinetic children responded to the stimulant by slowing down as if it were a sedative, their response was termed paradoxical. When Judy (alone of all of us with the courage to do the study!) put the matter to empirical test by giving dextroamphetamine to normal children (including several of her own), they slowed down just as the patients did (32). The "paradox" was age-related, not "disease"-related. That lesson continues to elude most child psychiatrists. A "therapeutic" response to the drug is taken as "confirmation" of a diagnosis. Are we converting a dimensional spectrum that covers the entire population arbitrarily into a diagnostic category? Have we become carpenters with hammers who see all problems as nails?

WHAT ESTABLISHED AND WHAT ERODED PSYCHOANALYTIC HEGEMONY?

When I completed my training in psychiatry, a half-century ago, psychoanalysis was in and genetics was out. Fifty years later, genetics is in and psychoanalysis is out. What happened? Did the change result from scientific progress? Science had a good deal to do with the blossoming of genetics, but economics proved decisive for practice.

How had an untestable theory and a treatment without proof of effectiveness come to be so dominant a half-century ago? Three characteristics of medicine (*all* of medicine, including psychiatry) in the 1950s help to explain it: treatment recommendations were based on "clinical experience" rather than exacting trials; there were few therapeutic alternatives in psychiatry and no equally comprehensive theory; and, most important of all, psychoanalysis taught psychiatrists to listen to their patients.

As to the first, treatment decisions in all of medicine as well as in psychiatry rested largely upon expert opinion (33). The first randomized clinical trial in medicine (on streptomycin for tuberculosis) was not published until 1948 (34).

As to the second, other than ECT, there were no reliably effective treatments for psychotic patients. Psychiatric patients were being warehoused in state mental hospitals in evergrowing numbers. So desperate was the state of affairs that more than 20,000 frontal lobotomies were performed in the United States in the 20 years following its introduction in 1936! What led to the abandonment of lobotomy was not the moral sensitivity of science, but rather the appearance of the dramatically effective psychotropic drugs that replaced it (35).

No other psychological theory provided as comprehensive an account of the origins of psychopathology. The brain sciences of the era were entirely irrelevant to clinical practice. Diagnosis was unreliable and made little difference for treatment. Psychoanalysis seemed to "explain" the bizarre symptoms patients exhibited. Its very complexity and counter-intuitiveness enhanced its allure. It connected the symptoms of mental illness to the psychopathology of everyday life.

As to the third, many patients improved when we listened to them and offered what other specialists derided as "talk therapy." Proof that talk therapies do work had to wait another 30 years. Psychiatry as a profession remained remarkably indifferent to the absence of empirical justification. Warnings that lack of data would threaten our credibility (and likelihood of being reimbursed for our services!) were simply ignored. In the late '60s I wrote (36):

> What is remarkable is how little effect these studies [of psychotherapy outcomes] with their scots verdict of "not proven" have had on professional practice. Surely … they should have led to … studies to define the indications for, the best methods of, and the limitations to, psychotherapy rather than what can only be compared to a religious conviction in possessing an exclusive road to salvation.

At the 1962 APA Conference on Psychiatric Training (37), I spoke from the floor at the final plenary session. During the preceding 4 days, there had been general agreement on the importance of further training in newly arising or rediscovered disciplines (psychopharmacology, sociology, anthropology); at the same time, the acknowledged shortage of psychiatrists and the financial burden precluded lengthening residency training. I made the obvious point that something had to go. No one had indicated what should be cut back to make room for the new, even though more sausage could not be squeezed into the same casing. Accordingly, I volunteered a modest proposal: namely, that the time devoted to psychoanalytic theory and practice be sharply reduced. I questioned psychoanalysis as a "science" because its propositions were formulated in such a way that they could not be disconfirmed. A didactic analysis for psychiatric house officers, I added, limited their geographic mobility, necessitated moonlighting to secure supplementary income, prepared them for practice patterns limited to middle-and upper class patients, turned them away from research because they had been fed readymade "answers," and isolated them

from public service (38).

I had never before, nor have I ever since, had such an electrifying effect on a professional audience. I was barely able to get out of the way of a veritable stampede of eminent department chairmen who lined up behind the floor microphones to challenge my facts, my conclusions, my credentials, and my lineage! (I say "chair*men*" advisedly; there was not a single chair*woman.*) My modest proposal disappeared with the merest trace: a footnote on page 8 of the Conference Report (37). However, by the 1976 APA Conference on training (39), the influence of psychoanalysis had ebbed markedly, not because of my or other theoretical challenges, but because of the rising tide of psychopharmacology.

REFLECTIONS ON MY CRITIQUE OF PSYCHOANALYSIS

Do I still believe what I said then? My scientific critique is unchanged. The "research" method of psychoanalysis follows none of the accepted scientific principles of prediction, design, control, and quantification. Freud's ideas had been revolutionary in their time, but "the history of science ... is replete with instances in which an initially liberating conceptualization, once institutionalized, becomes a barrier to progress" (40).

What I failed to acknowledge was the powerful and lasting contribution psychoanalysis had made to psychiatry by teaching trainees to listen to patients and to try to understand their distress, rather than merely to classify them with a diagnostic algorithm, or snow them with drugs, or lock them away, or release them to homelessness. Basing care on what is unique to the individual patient is central to clinical competence, whether in medicine or surgery or psychiatry. Psychoanalysis made a dynamic psychological approach central to general psychiatry. It emphasized the importance of memory, its vulnerability to distortion, and its centrality to each person's life narrative, the way we explain ourselves to ourselves and to others. Because those narratives can be self-defeating, therapy must be designed to help patients to reconstruct their autobiographies in ways that permit growth. Those principles remain as important in caring for patients today as they were then, but the paymasters of the healthcare marketplace are making time less and less available to patients (41). The economic barriers that hinder psychiatrists in providing psychotherapy have impoverished clinical psychiatry.

Psychoanalysis itself continues to do well in private institutes and conclaves, but it is largely missing from the academic scene in psychiatry, where it was once dominant (42). There has been, however, a sea change in psychotherapy research. Whereas there were no psychotherapies of proven efficacy 50 years ago (36), randomized controlled clinical trials have shown that a number of nonanalytic psychotherapies do work for particular disorders (43). Does the new evidence explain the recession of psychoanalysis? Not at all! Despite proof of efficacy, the

provision of any brand of psychotherapy is diminishing. HMOs and insurance companies simply won't pay for more than a soupcon. Psychiatrists now make DSM-IV diagnoses and prescribe drugs. Money is shaping practice (44).

I hope I have persuaded readers of the importance of skepticism toward received wisdom. Psychoanalysis circa 1950 was no more the royal road to salvation than the human genome project is 60 years later. The challenge is the integration of concepts of mind and brain: Can we invent paradigms that will give new meanings to an old term, "psychogenetic?" For that, we will need to provide an education for our successors that will bridge disciplines among the brain, behavioral, and clinical sciences (45). We would do well to heed the admonition of Sir Aubrey Lewis (46), late head of Maudsley Hospital in London:

> The philosophers thought it proper to put not one but two mottoes on the Temple at Delphi: one, the better remembered, was "Know Thyself": but the second, equally imperative, enjoined "Nothing in Excess." It might be worth inscribing that over the Temple of Psychiatry.

DREAMING AHEAD

What are my credentials as a futurologist? I offer a prediction I made 20 years ago (44), which readers can check against the two decades that have followed to make an informed decision about the believability of my dreams.

A PARABLE FOR OUR TIME

I invented a virtual experiment as a metaphor for a clear and impending danger: the threat that reliance on technology would replace concern for the patient and the patient's story (44). The starting point for the studies in our Laboratory of Mental Science was the neurobiological breakthrough by René Descartes, identifying the pineal glad as the seat of the soul (47).

> The part of the body in which the soul exercises its functions immediately is in nowise the heart, nor the whole of the brain, but merely the most inward of all its parts, to wit, a certain very small gland which is situated in the middle of its substance and so suspended above the duct whereby the animal spirits in its anterior cavities have communication with those in its posterior, that the slightest movements which take place in it may alter very greatly the course of these spirits; and reciprocally that the smallest changes which occur in the course of the spirits may do much to change the movements of this gland … The whole action of the soul consists of this, that solely because it desires something, it causes the little gland with which it is closely united to move in the way requisite to produce the

effect which relates to this desire.

Accordingly, our research team grew pineal cells in tissue culture and eluted a unique protein from the supernatant. Against this pineal-specific protein, we prepared a monoclonal antibody made radioactive by incubating the hybridoma cells with oxygen-labeled acetate. Administered parenterally, the tracer molecule, modified to permeate the blood-brain barrier in the region of the pineal body, binds to the gland tightly and specifically. As the positrons emitted by O collide with electrons in the adjacent tissues, the gamma rays produced by particle annihilation are detected and converted by appropriate instrumentation into a visual image. A major step forward occurred when our engineers succeeded in constructing a luminescent screen on which moment-to-moment changes could be displayed. Thus, displacements in the pineal (accompanied, as Descartes had predicted, by ventricular currents) could be correlated with fluctuations in the state of the soul.

That must suffice for an account of the science of the matter. Now consider its economics. The instrument, destined to be patented as *PinealPet®,* can be guaranteed to increase the earning capacity of American psychiatrists handsomely, when they work in a fee-for-service system. Because its immediate imaging properties make it ideal for office use, psychiatrists rather than radiologists can bill for it, and thus attain economic parity with other technology-based disciplines. Because it will no longer be necessary to inquire of the patient about the state of his or her soul, a notoriously time-consuming, uncertain, and altogether messy procedure, time savings will be prodigious; productivity will increase; cost-effectiveness will please both supply side and free market economics. For myself, I intended to ask no profit (other than the Nobel Prize money).

Furthermore, the therapeutic potential of this technological advance will not have escaped notice. It should prove possible, in principle, by a kind of psychochiropractic, to correct the subluxations of the pineal which result in existential *angst.* By means of the piezoelectric effect, the therapist should be able to manipulate the pineal body with pulses of current under direct visual control to align it in such fashion as to produce harmony in the soul.

Yet, at the very point that the device was ready to be marketed, I was afflicted by an acute crisis of conscience, in all probability resulting from *mal de mer* of the pineal. I melted the instrument down; I shredded blueprints and protocols before they could be copied by sinister commercial interests. In the nick of time, I had realized the consequences of my thought experiment. Once at hand, PinealPet, like the endoscope, the stent, and the cardiac catheter before it, would have come to dominate clinical practice through its potential for increasing earnings *and* its capacity to generate nominally objective data. A technology invested with the authority of science is irresistible to patient and doctor alike in reifying disease.

How good was that prediction? Psychochiropractics, of course, have not quite

arrived (though brain stimulation techniques are multiplying). There has been an enormous increase in technological capabilities for brain imaging. For an understanding of the brain-mind interface, that bodes only good. For practice, it carries the risk of premature application, as PinealPet did. What the thought experiment left out—until I at the very last moment "melted the instrument down and shredded the blueprints"—is *agency;* that is, the responsibility of physicians committed to patient care to resist and even roll back the tide of reductionism.

Until recently, financial subsidies from industry and uncontrolled access for pharmaceutical sales representatives have been "embedded" in departments of academic medicine much as journalists were with military units in the invasion of Iraq. The ubiquity of drug company-sponsored meals, lectures, and visits from PSRs during medical residency training represented a very considerable investment by the industry. Reflecting a conviction that this investment pays off, big Pharma has been spending two to three times as much on marketing and administration as it does on research and development (48,49). However, in the past 10 years, leading teaching hospitals have ended "pizza lunches" for house staff and have limited the access of drug detail representatives to faculty and house staff. Academic psychiatry is beginning to assert the primacy of evidence-based medicine and alerting physicians to the risks of seduction by gifts and blandishments.

In a second major step forward, the American Board of Psychiatry and Neurology now requires that residents demonstrate familiarity with and competence in a set of evidence-based psychotherapies, in addition to competence in psychopharmacology. The impact of this requirement depends on progress in developing reliable measures of competence and making these measures a key to accreditation. Once again, it will be up to all of us to assure the achievement of that goal.

A third major deficit in academic psychiatry—the decades-long decline in the number of psychiatrist-investigators—is being addressed in a serious and credible way. In 2003, the Institute of Medicine issued a scholarly document *Research Training in Psychiatry Residency: Strategies for Reform* (50). Among its many excellent recommendations (51) was a proposal that a public-private consortium be created to carry the program forward. With support from NIMH and leading psychiatric societies, precisely such a consortium was created: the National Psychiatry Training Council. In 2005, it completed its work with a report, *Educating a New Generation of Psychiatrist Investigators* (52). Its recommendations include a call for the Residency Review Committee to give greater flexibility to program directors in designing the order of training (so that child and adolescent training within the first 2 years counts toward subspecialty training, for example) and to permit the creation of research tracks by shortening mandated requirements. No less important, it emphasizes that "research literacy" be made the goal for all residents. To reinforce that proposal, the ABPN examination must include questions to demonstrate literacy in assessing methodology and outcome of research protocols. It

calls for a "national academy" of senior research mentors to be available on an ad hoc basis to all trainees.

These recommendations have been presented at a number of professional psychiatric meetings; several model child psychiatry research training fellowships have come into being, the most notable being the Albert J. Solnit Integrated Child and Adult Research Residency Pathway at the Yale Child Study Center (53). Once again, how far this effort to recruit a new generation of child psychiatry investigators will proceed will depend upon the support it receives from the old (faculty) as well as the young (students in training). Our fate is in ourselves, not in our stars.

THE FUTURE OF PATIENT CARE: ECONOMICS AND ETHICS

Nothing has shaken my conviction that the superiority of patient-centered, psychologically sensitive, integrative medicine will become ever more evident. Patients as well as physicians will serve as its advocates and assure its ascendancy. In his surrealistic short story, *A Country Doctor,* written early in the last century, Franz Kafka wrote: "To write prescriptions is easy; to come to an understanding with people is difficult." The first part of the aphorism no longer rings quite true; choosing the right prescription for the individual patient at the appropriate moment is a real challenge in an era when we have powerful medications (with powerful side effects) at our command. However, it remains true that coming to an understanding with people is even more difficult and demands more time than writing a script. Time is the essence of good medical care. It is time that is at threat.

I conclude with a passage from Plato's *The Laws,* written about 350 BC (54). An Athenian "Stranger" addresses Cleinias, a Cretan, and Megillus, a Spartan. The Athenian Stranger (in effect, Plato himself) has this to say about "slave" and "free" physicians in Greek society:

> Slaves … are almost always treated by other slaves who either rush about on flying visits or wait to be consulted in their surgeries. This kind of doctor never gives any account of the particular illness of the individual slave, or is prepared to listen to one; he simply prescribes what he thinks best in the light of experience, as if he had precise knowledge, and with the self-confidence of a dictator. Then he dashes off on his way to the next slave-patient, and so takes off his master's shoulders some of the work of attending the sick.
>
> The visits of the free doctor, by contrast, are mostly concerned with treating the illnesses of free men; *his* method is to construct an empirical case history by consulting the invalid and his friends; in this way he himself learns something from the sick and at the same time he gives the individual patient all the instruction he can. He gives no prescription until he has somehow gained the invalid's consent;

then, coaxing him into continued cooperation, he tries to complete his restoration to health.

The Stranger asks: “Which of the two methods do you think makes a doctor a better healer ...?”

The reader of this textbook will have no difficulty in choosing the preferred option. In return for what that reader has learned, he and she have incurred an obligation: to fight to preserve that option. Commitment to assuring children access to the best professional care is the precondition for child psychiatry to flourish.
